Psychologically early childhood is associated with continued cognitive development, including refinements of language, executive control, and sense of self. Because cognitive development continues processes started during infancy and the energetic demands of the brain start increasing at birth and continue until the age of 5, and because 5 years is the cutoff for kindergarten, sometimes infancy and early childhood are combined in a single stage referred to as “under-5 s.” This breaks down the assumption of a discrete age-related boundary between early and middle childhood and leads to what is known as the 5 to 8 transition discussed below.

Middle Childhood. Entry into middle childhood is associated with the 5 to 8 transition, termed the age of reason and responsibility by Sheldon White (White 1996) because it is the beginning of children's capacity to reason and act according to social rules. This shift is recognized in the Catholic Church by the rite of confirmation which marks the child's capacity for moral reasoning and in our larger culture by the beginning of formal schooling which marks the child's ability to learn and retain knowledge. In fact, Lancy and Grove (2011) report that some societies say that before the age of 6, children are stupid and have no common sense. Given that common sense

is by its nature culturally defined, this statement captures the onset of socialization during this stage.

In terms of cognitive development, middle childhood is associated with the onset of metallization or the capacity to think about thoughts, a key human cultural capacity, associated with the development of the right temporoparietal junction (Saxe et al. 2009). It also marks the beginning of a long process of cortical maturation that stretches into the mid-20s (Gogtay et al. 2004) which underlies the capacity for cognitive development throughout childhood and into young adulthood (Shaw et al. 2006). Middle childhood is also marked by adrenarche, or the onset of production of adrenal androgens, which has been related to the maturation of the tempoparietal junction from the age of 7 to 12 years (Nguyen et al. 2013).

Adolescence. Adolescence (12 to 18 years) serves as a good example of the overlapping of cultural, social, and biological levels of human life stages. Biologically, adolescence is defined by puberty and reproductive maturation, while adolescence as a social category is the transition from childhood dependence to adult independence including such things as entry in high school and being just competent for driving, drinking, and military service. Culturally, adolescence also includes the onset of family formation and reproduction. It is important to recognize that unlike early life stages which involve subtle physical and behavioral changes most recognizable to those familiar with the developing child, puberty is easily recognized by a wide range of others. Secondary sexual characteristics are obvious signals that invite a response by others, whether as a possible sexual partner, as a physically mature adult, or as potential troublemakers.

Puberty itself is variable in timing with some individuals starting to show the earliest development of secondary sexual characteristics by the age of 10 and some not until 15 years. In addition, on average boys mature about 2 years later than girls. Gonadal maturation is associated with the rise in testosterone in males and estrogen and progesterone in females. These hormones lead to the development of secondary sexual characteristics such as the development of breasts and hip

among girls and facial hair and voice changes in boys. In addition, rising hormone levels are associated with a growth spurt in height. The spurt is fueled by the effects of androgens on bone growth and cutoff by rising estrogens, meaning that girls not only stop growing earlier than boys but on average attain shorter adult heights than do boys (Bogin 1999).

Behaviorally, increases in testosterone have also been associated with increased sexual behavior in both boys and girls even when controlled for pubertal stage (Halpern et al. 1997, 1998). This suggests that changes in individual sexual motivation play a role in sexual initiation in both sexes, alongside social factors such as SES, ethnicity, and religiosity (Halpern et al. 1994).

In addition to sexual behavior, adolescents and especially male adolescents are well-known for high levels of risk-taking and antisocial behavior. Such risk-taking appears to represent the differential timing of increases in cognitive capacity and social maturity. Steinberg (Steinberg et al. 2008) documents a more or less continuous increases in intellectual capacity from 10 years into the late 20s, while measures of psychosocial maturity plateau from 10 to 21 years and only then begin to climb throughout the 20s. More detailed measures show that planning ahead actually reaches a nadir in mid-puberty and then increases into the 20s (Steinberg 2010).

Adulthood. Adulthood is the species defining life stage, with adults recognized as fully functioning members of society in terms of both production and reproduction. Yet, the biological underpinnings of reproduction and production vary across adulthood. As soon as adulthood is reached, individuals start undergoing senescence, defined as declining functional capacity, including the soma, brain, and reproduction, but may continue to increase their knowledge, social networks, and status.

In contrast to development which is a highly orchestrated interplay of somatic, cognitive, and reproduction process with a defined length of time in order to maximize the possibility of reproduction, senescence reflects a much less controlled devolution of bodily function resulting in greater individual variation in the process. Thus

environmental factors such as activity, education, and social support are important determinants of the rate of senescence.

Adulthood is usually divided in three stages: young adulthood (20–40), middle age (40–60 years), and old age (60 onward). It is important to recognize that the age boundaries are as much for the purpose of definition as they are specific events and that the relationship between the biological and social definition of the stages can be fuzzy. For instance, if adulthood is defined as the end of puberty, it can be said to start at 18 years. On the other hand, if adulthood is defined as being held legally accountable for one's actions, then adulthood starts at 21 years. In another example, the onset of old age is 60 years when defined by an increasing rate of senescence decline both physically and cognitively, but 65 if defined by retirement and a decrease in economic productivity.

Socially, young adulthood is defined by employment, family formation, and reproduction. Thus this stage may be the stage most directly associated with changes in economic structures across cultures and at the same time the one most subject to cultural categorization. In many subsistence societies, the onset of these activities may be more or less synchronous with physical maturity with food production by the male necessary for family formation and reproduction, though not always in that order.

On the other hand, the lengthening of education and the delay in careers and marriage in industrialized societies mean that these activities are no longer closely tied to physical maturity. Hence Jeffery Arnett (2000) has suggested an additional stage which he refers to as emerging adulthood. Emerging adulthood is considered to result from ongoing social changes in education and career development that put off family formation and hence fully recognized adulthood.

However, recent findings demonstrate that maturation of the brain cortex continues to develop into the mid-20s (Gogtay et al. 2004), suggesting an underlying biological basis for such a stage. Coupled with the increases in psychosocial maturity in the 20s mentioned above, such changes in the brain suggest that emerging

adulthood is not simply a novel product of social change but a more biologically defined aspect of entry into the young adult stage.

At the other end of young adulthood, the transition to middle age is defined by the end of family formation. The average age of last reproduction for women is around 40 years, though fertility has been declining since the early 30s. In men there is much less evidence for a decline in reproductive capacity, but in monogamous relationships reproduction itself is tied to the women's age. While physical and cognitive functions decline in both men and women throughout young adulthood, the decline itself does not define the life stage.

Middle adulthood (40–60 years) is marked by important changes in the nature of family, along with increased economic productivity. Children born during young adulthood will now be in young adulthood themselves, shifting the nature of continued parental concerns and help. At the same time, aging parents may require everyday support for themselves. No wonder Erikson characterized this stage as one of caring.

Some research suggests a plateau in decline of cognitive functions during this stage including men such as word recall, matrix reasoning, spatial relations, and pattern comparison in both men and women during this stage.

Biologically, old age (60+ years) is defined by an increasing rate of senescence. This includes increasing decline in muscle mass in men and fluid intelligence in both sexes. The cognitive changes are underlain by changes in the brain, most notably a decline in white matter starting around the age of 50. Cognitively, the decline in fluid intelligences is countered by an increase in crystallized intelligence. This is notable in occupations characterized by knowledge production such as academics where some individuals remain productive well into old age. However, socially old age is marked by a loss of productivity, signaled by a retirement age of 65.

More generally old age is marked by an increase in wisdom along with increasing physical frailty. The fact that among hunter-gatherers some individuals live into their 80s indicates that this is a normal phase of the human life cycle and not simply an artifact of our modern conditions.

Those individuals who manage to survive into later age have been successful in doing so. Thus the result of their experience is not just accumulated cultural knowledge but by definition wisdom. Nonetheless, for many the last stage of old age will be defined as loss of self-sufficiency and an involuntary withdrawal from the social world as friends die. What is left but to concentrate on one's self and the inevitability of death?

This brings us to one of the most distinctive elements of the human life cycle: menopause. The complete cessation of reproductive function before death is rare among mammals. Thus human menopause raises the question of how such a state can be produced by natural selection. The grandmother hypothesis (Hawkes 2003) suggests that human females remain alive past their reproductive years because they provide help to their daughter's offspring. The grandchildren's survival then promotes selection for the genes underlying longevity. Whether this selection pressure is sufficient to generate a post-reproductive life span of 40 or more years among ancestral hunter-gathers is unclear. On the other hand, it does appear that grandmothers do result in more offspring surviving in some societies where the hypothesis has been tested.

Comparative Biology. Human life stages come into clearer evolutionary perspective when contrasted with our closest relatives, the great apes, in particular chimpanzees, for whom we have quite a bit of information. At about 250 days, gestation in the chimp is roughly the same length as for humans, suggesting similar prenatal development. Development of the brain in human is much more rapid during the last trimester compared to chimpanzees (Sakai et al. 2012). This suggests that continued brain development during the last trimester represents a relatively recent evolutionary phenomenon and may be important to the development of the brain after birth as well.

Weaning in chimpanzees is at about 5 years of age and reproductive maturation for females at close to 12 years (Walker et al. 2018). Thus the development of early childhood in human reflects an additional life stage inserted into the ancestral pattern. Such a change has two important

implications. First of all human infants spend less time with their mothers and more with other family members. In addition the prolonged period of development from weaning to puberty is associated with slower somatic growth rates (Walker et al. 2006) that allows for an extended period of brain maturation. In turn extended development suggests that the human brain can be shaped by environmental inputs during childhood increasing the importance of learning.

Comparison of the timing of reproduction among adult female humans with those of chimps is instructive about the evolutionary origins of human old age. Human females mature later but have higher age-specific fertility throughout their peak reproductive years, but the average age at last birth is close to 40 about the same age as human females (Hawkes 2010). Yet, even among hunter-gatherers, human females continue to live for up to 40 more years, while female chimpanzees rarely outlive the end of their reproductive capacity (Hill et al. 2001).

Importantly, a comparison of humans and chimps reveals that humans show a decrease in brain volume with age while chimpanzees do not, suggesting that the human brain undergoes senescent decline as a result of our extended life span (Sherwood et al. 2011), just as the human body does. In contrast, the chimpanzee brain appears to maintain more or less function until bodily and reproductive demise around the age of 50 years.

Interestingly, life satisfaction among captive great apes including chimpanzees shows a u-shaped curve with lowest levels during middle age (Weiss et al. 2012) just as it does among humans (Blanchflower and Oswald 2008). The authors characterize the nadir in life satisfaction as a midlife crisis, but it seems more accurate to point out that it reflects important changes in the demands of raising offspring.

Conclusion

Life stages are a cultural categorization of the inevitable changes experienced by individuals over their lifespan. While life stages represent culturally defined categories, current thinking

emphasizes eight distinct stages, including prenatal, infancy, early and middle childhood, adolescence, and young, middle, and old adulthood, characterized by biological, psychological, and social dimensions. An increasing understanding of the brain and hormonal changes provides a species-specific biological underpinning for these stages. Comparison with chimpanzees suggests the emergence of two new life stages in the last six million years of hominid evolution. These include the insertion of an early childhood phase between infancy and middle childhood that is characterized by continued development of the brain no longer dependent on the mothers the context of close relatives. It also includes old age, most clearly demonstrated by an extended postmenopausal female life stage.

Definition

The concept of Standard Social Science Model (SSSM) is used for description of the basic theoretical assumptions that determine the specific focus of consideration of social and cultural phenomena in psychology and social science for twentieth century. The core of SSSM is formed by the idea about the human mind as a blank slate and the related concept on exclusive role of the social world and culture in the formation of its content.

Introduction

The concept of Standard Social Science Model was first introduced by John Tooby and Leda Cosmides in 1992 (Tooby and Cosmides 1992, 1997) for identifying the epistemological framework of

social science and psychological studies of the twentieth century. According to them, its representatives are excessive concentrated on the social and cultural factors while denying any influence of biological one in their research. Tooby and Cosmides determined this view as a source of separation between social and natural sciences and one of the major obstacles for social science progress now. Moreover, social scholars used the idea on the sufficiency of social factors for the explanation of human behavior (such view is especially strong in sociology starting from sociologism of Emile Durkheim) as the way to establish and then to maintain disciplinary autonomy.

Tooby and Cosmides (1992) put into the core of SSSM an idea of the human mind as a blank slate (or, in Latin, as British philosopher of the seventeenth century John Locke said “*tabula rasa*”), i.e., the proposition that humans are born without any predispositions toward certain social perception, social cognition, and social behavior. Pinker (2016) also argued that the blank slate is accompanied by two other doctrines such as the concept of Noble Savage (J.-J. Rousseau, T. Hobbes) and the concept of the Ghost in the Machine (R. Descartes). Thus, the next logically related idea is that social factors and culture determine how and what we percept and learn and how we behave. Pinker also put this idea in relativist framework as SSSM supports the idea on the connection between variations in culture and the content of the human minds. At last, SSSM also proposed that human mind has no evolved structure, considering it as an externally programmed general-purpose device for learning.

According to Steven Pinker (2016), SSSM began to dominate in the intellectual life since the 1920s. He named among the most famous founders and supporters of SSSM anthropologist Margaret Mead, behaviorist psychologist John Watson and Burrhus R. Skinner (Pinker 2007). To this list, we can also add one of the fathers of social interactionism George H. Mead, who is considered as a social behaviorist. Besides, Pinker named such modern scientists from different disciplines as Richard Lewontin, Stephen Jay Gould, Steven Rose, and Leo Kamin as proponents of SSSM.

This entry describes the main assumptions of SSSM as they described by Tooby and Cosmides (1992), as well as reflected in the context of critical consideration of Pinker (2016, 2007). It is also considered the alternative nativist models proposed by them that largely supported by the recent progress in the studies of neurobiological mechanisms of the social behavior and the development of evolutionary psychology. At the end of the entries, some critical views on the dichotomy between Standard Social Science Model and the alternative Integrative Causal Model are discussed.

The Main Assumptions of Standard Social Science Model

Analyzing considerations that motivated the advocates of SSSM, Tooby and Cosmides identified the main features of the social sciences view in this framework (Tooby and Cosmides 1992, pp. 25–31):

1. The psychic unity of humankind. According to this note, the human infants all around the world are born identical in their basic human design and the development potential. As genetic variation cannot explain the extreme differences in thought and behavior between groups and the similarity within groups, social scholars put social factors and culture into first place. They forward these factors as responsible for inter-group differences.
2. Human nature has no casual significance in mental organization, social arrangements, culture, and so on. According to Tooby and Cosmides, this statement looks as a result of the logical trick.

Thus, the supporters of SSSM conclude that evolved structure of the human mind has no influence on inter-group differences in mental and social organization in adults as infants have the same biological nature.

3. The humans acquire knowledge, patterned social behavior, etc. from outside in the process of their development (SSSM considers only ability to learn among infants). In this, the external factors are considered only

source for human mental transformation. This statement is deduced from the lack of any complex mental organization in infants in comparison with adults.

4. Social world is the cause for mental organization of the adults. Such conclusion is based on two propositions. First, what we see as a mental organization in the infants is “innate,” i.e., inborn or genetically determined, etc., while in adults, it is formed under the influence of environmental factors. Thus, SSSM states cultural phenomena, fundamentally, have no heredity and are only acquired. Second, based on the deprivation thought experiments, SSSM supports that humans without being programmed by culture demonstrate “virtually ungovernable, a mere chaos of pointless acts and exploding emotions, his experience virtually shapeless” (Tooby and Cosmides 1992, p. 26). Once the factor of culture appears, the individuals change and become socially organized and predicted. This leads the supporters of SSSM to conclusion on the fundamental role of culture in the shaping of mental organization in adults.
5. There is overwhelmingly or entirely one direction of causation: socially organized environment and culture precede the existence of the individuals and are external to them; they determine or construct them. At the same time, this influence is unidirectional – when we are born, we find certain social and cultural circumstances. From this, the advocates of SSSM conclude that the individual (mind) cannot create the social world and only follow its settings, the last create the individual (mind). Individuals are in the situation of social coercivity (for the first time, this idea was clearly formulated by Emile Durkheim in 1895 in his work *The Rules of Sociological Method*, who said about coercion considering crucial influence of social facts on the individuals). As Tooby and Cosmides exemplify, according to SSSM, we have no choice what native language to learn or we cannot to create new language. Moreover, from the observation of the strong influence of sociocultural or political processes in modern society on the individuals in contrast to the influence of the individuals on them, the supporters of SSSM conclude that “the sociocultural world is the actor (the cause or the prior state that determines the subsequent state)” (Tooby and Cosmides 1992, p. 26).
6. As culture is the only one that has a matter in shaping the human mind and behavior, then it only deserves our examination. SSSM interprets culture in different ways, for example, as economic relations, political regimes, meaningful symbolic system, social relations, social institutes and norms, traditions, knowledge, and so on. At the same time, it is always considered as nonbiological entity (nonbiological in its origin and its nature). Interesting moment here is that not only the above staff of culture is external to the individuals, but is also such psychological phenomena as thinking too. The last means that our thinking is to a large extent social and public, consists of significant culturally determined symbols and in the most part of the words (this idea is well elaborated on by George H. Mead).
7. The individual is not a creator of a complex and significant organization in the social world. As Durkheim noted “once the individual is ruled out, only society remains” (Durkheim 1982, p.182). Such position is marked now as sociological realism (contrary to social nominalism). In sociological realism, the “collective concepts” such as society, social class, state, social organization, etc. capture the real existence of supra-individual phenomena. They are considered as more than the sum of the individuals. Advocates of social realism believe in objective regularities in the social world and its independence from the individuals.
8. Sociocultural phenomena are generated by other phenomena at the sociocultural level. Thus, sociocultural reality is a reality *sui generis*, which can be explained in the terms of itself. Such position was forwarded by many social scholars in different disciplines. Thus, Durkheim developed sociological

conception named sociologism, which includes ontological and methodological aspects. In ontological sense, society was analyzed as a special kind of reality that cannot be reduced to its other types. He insisted on the top priority of social reality over the individuals (i.e., over biopsychic reality that is implemented in the individuals). Methodological aspect of sociologism includes guiding principle for social science studies. According to this principle, social facts must be explained only by other social facts, without any references to psychic phenomena, or something like that. In Durkheim's view, it is quite enough for understanding the social phenomena. It is also important that he considered social facts as things: they exist independent from the individuals, but influence on them.

9. Human nature (the evolved architecture of the human mind) is only a necessary condition for the organization of social life; however, it does not play any notable role in its configuration. The role of the human nature (or human mind) is only in the ability for learning and incorporating the culture. Moreover, the human mind is formless, malleable, and plastic phenomenon that is enough, easily formed by sociocultural factors in the process of socialization. Then, the human mind is considered as a general-purpose computer that is programmed for learning certain types of behavior by culture and so controlled by outside mechanisms. In SSSM, this idea is connected with a view on the human mind as an empty vessel, which is waiting to be filled by knowledge, social norms, behavioral patterns, and so on. Thus, the mind itself is not a problem or subject of investigation in SSSM. The main problem is cultural or social circumstances that determine it.
10. Learning is the basic mechanism of incorporation of "the culturally manufactured pre-existing complex organization outside of the individual" (Tooby and Cosmides 1992, p. 30) into the human. Consequently, the role of psychology is to provide knowledge about the process of such learning. In such

perspective, the human mind, if it is at all inborn equipped, must have such mechanisms or structure that enable individuals to absorb any environmental influences. At the same time, the human mind organization could not shape the content of culture or even be predisposed to the certain selection of cultural inputs (e.g., what to learn and what not). According to Tooby and Cosmides, the psychological studies of the general laws of learning (and underlying cognitive processes) had positive effects on the bringing psychology and natural sciences closer together.

As Hampton (2004) summarized, the SSSM states "(a) that mind, aside its capacity to learn, is a tabula rasa; (b) that culture is the cause of mental content; (c) that culture is independent of mind; and (d) that psychology should be concerned with the study of enculturation" (Hampton 2004, p. 17).

Steven Pinker, modern advocacy of evolutionary psychology and the computational theory of mind, refers to the concept of Standard Social Science Model to advance his own an alternative view on the human nature (about this below). He describes SSSM as a relativist perspective in which the human nature is lacking universal essence, i.e., its content is very malleable and varies according to culture, society, and historical situation and does not possess fixed structure. In popular-science book "The Language Instinct" (2007), Pinker lists the significant points of SSSM, which he finds problematic:

1. Human behavior (in contrast to animal) is determined by only "free from biological constraints" culture, which can vary "arbitrarily and without limit" (Pinker 1994, p. 406).
2. A few reflexes and an ability to learn are only inborn human infants who learn the culture in the process of socialization (Pinker 1994, p. 406).

For Pinker, "SSSM has not only been the foundation of the study of humankind within the academy, but serves as the secular ideology of our age, the position on human nature that any decent person should hold" (Pinker 1994, p. 406).

SSSM is considered as an alternative to “biological determinism” that is treated as having harmful social effects contributing to different forms of social discriminations, supporting social inequality, promoting racist or imperialist ideologies, and initiated such horrors of the twentieth century as human forced sterilization and genocide.

Such taboo on human nature “put blinkers on researchers” and “turned any discussion of it into a heresy that must be stamped out” (Pinker 2016, p. xi). In “The Blank Slate: The Modern Denial of Human Nature” (2016) Pinker also proposed that different types of fear such as the fear of inequality, the fear of imperfectability, the fear of determinism, and the fear of nihilism are the sources of the notion that human mind does not have innate traits. He also called for “realistic biologically informed humanism” considering many negative social and political effects of the elimination of human nature as an important basis for social decision-making.

The philosophers Mallon and Stich (2000) use the term of “social constructionism” as a label for those who advocate the most assumptions of SSSM, but do it in more constructive manner. As they said, all SSSM followers are social constructionists, though not all social constructionists share every aspect of SSSM. Social constructionists do not deny innate “mental endowment imposes some constraints on what we can learn and what we can do” (Mallon and Stich 2000, p. 134); however, they believe that for “explaining the diversity of psychological phenomena like emotions, beliefs, and preferences, differences in the surrounding culture loom large” (Mallon and Stich 2000, p. 134). The different aspects of social constructionism and six graduations (historical, ironic, reformist, unmasking, rebellious, revolutionary) of the using of construction ideas are analyzed by Hacking (1999).

Alternative Integrated Model

Tooby and Cosmides (1992) critically estimate the basic ideas of Standard Social Science Model.

The central points of Tooby and Cosmides’ critiques of SSSM are (1) its isolationism, i.e.,

SSSM has failed to integrate itself with other sciences or even to acknowledge the necessity to be consistent and compatible with them, (2) its neglect to biology that is mostly motivated by moral and political concerns, and (3) its requirement an impossible psychology, “it posits theories of the human mind that cannot account for abilities we are already known to possess, and that also never could have evolved” (Scher and Rausche 2003, p. 233). Thus, they criticize SSSM for abandonment of any biological influences in the human mind and social behavior and for overestimation of the environmental factors. They also note that SSSM is one of the key factors of a lack of progress in social science now.

Indeed, recently biosociological sub-disciplines such as neurosociology, evolutionary sociology, social studies of genomics, etc. have started to develop. Their representatives try to incorporate biological variables into the sociological conceptions and theorizing, considering different dimensions of social behavior at micro- and macro- levels in the terms of the evolved adaptations strictly embedded in the neural activity of the human brain. The social scholars of these new areas talk about great difficulties to make sociology close to biological sciences. Many of them faced misunderstanding, difficulties in the publication of their research results and even discrimination from the colleagues (e.g., Kalkhoff et al. 2012; Massey 2013; Udry 2001). Such oppressive reaction is mostly determined by biophobia that is widespread in the sociological community. Biophobia means unjustified avoidance of using biological variables in the sociological studies, intolerant attitudes toward those who conduct such research. The causes of biophobia are rooted precisely in the basic assumptions of SSSM. Ellis (1996) determine such causes as semantic factors (i.e., “tendency to equate sociological with social causes”), lack of training in biology, exclusive focus on humans, and moral or political factors. The latter “involves a strong moral/ideological commitment to human equality that prevents many sociologists from considering the possibility of biologically based causes of individual and especially group differences in behavior” (Ellis 1996, p. 24). Moreover, biophobia (or as Ellis

also put “pure environmentalism”) lead to theoretical sterility and sociology’s decline (Ellis 1996). Sociologists conducting bisociological research certainly challenge the fundamental principles of sociological science. As Machalek and Martin (2015) emphasize, they had to adjust SSSM which supports a simplified dualism – learning vs. instinct, culture vs. biology, social vs. psychological factors of human behavior. Thus, the representatives of evolutionary sociology question the possibility to find the causes of social behavior exclusively in the social structure. They reduce the level of significance of the cultural factor in the determination of social behavior. The obtained results (e.g., Hopcroft 2018; Turner and Machalek 2018) are also clearly demonstrated that there are evolved biological predispositions to organizing themselves into social rank-ordered systems, male dominance, territoriality, aggression, sexual and reproduction social behaviors, emotionally based social relations, etc.

Thus, due to recent advancement in the studies of the evolved neurobiological mechanisms of social cognition, social perception, and social behavior in evolutionary psychology, cognitive and development psychology, as well as neurobiology and the related disciplines, the changes have taken place. These changes potentially can lead to formulate more balanced and complete epistemological basis for social science (as we can already see in the biosociological research).

Tooby and Cosmides (1992) proposed the Integrated Causal Model (ICM) on the position of SSSM, also known as Integrated Model (IM), where they merged biological and cultural factors considering the human mind and behavior in the terms of the evolved mechanisms, as well behavioral and psychological adaptations.

According to Tooby and Cosmides, only the first idea of SSSM about the biological identity in the infant design and development potential is correct. Therefore, it is included into the ICM without modification. This note is supported by the Human Genome Project and recent studies which highlighted the basic genetic similarity of all humans. Thus, “genetic variation does not explain why human groups dramatically differ from each other in thought and behavior” (Tooby and Cosmides (1992, p. 25).

The Integrated Causal Model includes the following main assumptions:

1. The human mind is a set of evolved information-processing mechanisms which have neurophysiological basis.
2. These mechanisms are adaptations obtained by the humans in the process of evolution and contributed to their survival.
3. The information-processing mechanisms of the human mind is specialized on solving particular adaptive problems.
4. Largely due to such specialization, they have content-specific structure.
5. According to this content specialization, the human mind produced specific content of the culture.
6. Such generated cultural content is then adopted or modified by psychological mechanisms in accordance with specific environment (Tooby and Cosmides 1992, p. 24).

Close to the Integrated Causal Model, the alternative perspectives have been developed by Pinker and some other nativist scientists. As Rosenberg notes, they treat the mind as “a package of a large number of different special-purpose instruments, each with its own independent domain of operation, each the developmental result of a distinct package of genes that were selected for by the evolutionary environment from which *Homo sapiens* and its immediate ancestors emerged”. (Rosenberg 2016, p. 226). Again, in contrast to SSSM, in nativist models (ICM is among such models too), the human mind/brain is modulated, structured and hardwired by the environment (including social setting and culture) under pressure of evolutionary factors. The humans at birth have already hardwired brain (consists of functionally specialized modules) that predisposed them to certain social perception, cognition, and behavior.

Thus, the human mind as a blank slate is replaced by the human mind as a set of the evolved adaptations strictly associated with neurophysiological processes. These adaptations reflect in the mind in the form of functionally structured information-processing mechanisms.

In contrast to SSSM, in alternative models, the human mind is a content specialized (not generally-purpose and only specialized for learning) machine. Then, ICM contrasts the note about human behavior as derived from the interactions between evolved psychological mechanisms and environmental (including, of course, cultural and social) factors with the idea about the human mind as culturally programmed in the process of learning. Further, culture has influence not only on the human nature, but at the same time it is also constructed by it. At last, the consideration of biological factors of human behavior is considered as important for its understanding in the alternative integrated models, but is not in the SSSM.

Criticism of the View on Social Science Through the Lens of SSSM

Richardson (2007) criticizes Tooby and Cosmides for that they proposed false dichotomy between “manifestly untenable view and their own” (Richardson 2007, p. 176) counterposing SSSM and ICM. According to him, in fact, Tooby and Cosmides had not proposed alternative as SSSM in their description is not in accordance with the real situation in social sciences and is not supported by scholars in the twentieth century. Richardson notes that hardly anybody really share the view on human mind as “general-purpose cognitive mechanisms, which lack any nativist element whatsoever” and that “no differences between individuals and no biological contribution to individual or social development” (Richardson 2007, p. 176).

Another line of critique is the interpretation of the political decision-making as a consequence of the implicitly or explicitly adapted SSSM view. Such critique is in Sampson’s work (2009), who based it on the dissection of the Pinker’s version of SSSM (“the idea that the mind is like a passive camera film”) and its role in society and science. Sampson (2009) says that the statement about domination of the SSSM as a “secular ideology” is untenable at least relative to some cultures (he said about Britain). Thus, he notes that in the

twentieth century (until 1990s) in education sphere, an idea about existing of natural children bents that need development are prevailed. Besides, although SSSM perhaps promotes to overcoming the role differences between sexes, women movements also began in the late 1960s (not as Pinker put it in the 1920th) and has become an influence only in the last decades, in the period when SSSM was started to be replaced by nativism philosophy. Therefore, they cannot be considered as practical implementation of the SSSM idea on the biological emptiness of the human mind. Sampson (2009) also ironized that the greatest founders (M. Mead, Watson) and advocates (Skinner) of SSSM (as Pinker point out) are hardly among the most influential thinkers of the twentieth century. At last, he (as well as Richardson (2007)) blames Pinker in “an appallingly crude version of empiricism – not a version that any serious thinker is likely to defend” (Sampson 2009, p. 132).

Neil Levy (2004) also says about overestimation of the role of SSSM in the intellectual life, as it was described by Pinker and his misleading in attributing Skinner to this view. According to Levy, “even behaviorists believe that the human mind has in-built learning mechanisms and preferences” (Levy 2004, p. 461). Without denying the differences between the basic assumptions of evolutionary psychology and SSSM, he emphasizes that nobody really shares the ideas of only one of the sides of the nature-nurture debates, at least in its extreme forms. Thus, everyone agrees that genetic factors influence the behavioral and psychic traits of the human in a probabilistic way, in accordance with the features of the environment (Levy 2004).

Hilary Rose (2001) emphasizes that Tooby and Cosmides in their assertions perverse the situation in sociological and anthropological studies considering it as concentrated on the nature-nurture debate. However, according to Rose, sociology and anthropology have not been at all very interested in the heritability factor over the last 50 years. The nature-nurture debate was rather a question for “Anglo-Saxon” psychometrics” (Galton, etc.) which aimed at measuring the so-called hereditary genius. Rose also surprised

about the adherents of SSSM how they were determined by Tooby and Cosmides. This especially concerns evolutionary paleontologist Stephen Jay Gould, the population genetics Richard Lewontin, the neurobiologist Steven Rose, and the psychologist Leo Kamin. The latter three scholars developed an alternative dialectical conception (opposite to biological determinism) considering dialectical relation between biological organism and environment. According to Rose, their dialectical view is more adequate than the Integrative Model of Tooby and Cosmides.

Thus, the main points of criticism concern how Tooby and Cosmides, as well as Pinker put the assumptions of SSSM into the intellectual framework of the twentieth century rather than its content. According to the aforementioned scholars, they do not correctly reflect on the mainstream ideas dominated in social sciences and reduced it to nature-nurture debate.

Conclusion

Standard Social Science Model is a concept used for describing the specific view of those social scholars and psychologists who give top priority to social and cultural factors in the formation of human mind and thus eliminate any evolved predispositions as well as biological factors in their considerations. SSSM is considered not only as a set of basic principles for social science studies but also as a theoretical basis for the dominant secular ideology. The major assumption lying in the foundation of SSSM is the human mind as a blank slate or *tabula rasa* in the term of philosopher John Locke. The human mind has no innate traits and its biological nature is unimportant for understanding human behavior.

SSSM was developed as an opposition to biological determinism and extremely dominant in social sciences in the twentieth century. But situation recently changes largely due to the progress in evolutionary psychology, and the related disciplines. Its development has been made possible after approving the idea on the evolutionary nature not only the human body but also the mind which is considered as connected with evolved neurophysiological basis.

Based on this idea, the authors of the concept “Standard Social Science Model” Tooby and Cosmides proposed the alternative view for social sciences. They named it the Integrated Causal Model. Thus, Tooby and Cosmides replaced the idea on the human mind as a blank slate by the note on the human mind as a set of evolved adaptations which contributed to the survival of our ancestors. Then, to the human mind as a general-purpose device, they contrasted the functional specialized information-processing mechanisms. At last, the assumption about independence of culture from any influences of the human biological nature was replaced by the idea of its dependence on the content-specific structure of the human mind which is specialized on solving different adaptive problems. Besides, based on the recent findings in neurobiology, the Integrated Causal Model takes as a starting point an idea that evolved information-processing mechanisms of the human mind strongly associated with neurophysiological activity. The similar ideas are also forwarded in other alternative nativist models (e.g., by Pinker).

Some modern scholars (e.g., Rose, Richardson, Levy, and Sampson) criticize the authors of the concept of Social Science Standard Model for that they formulated a simplified view on the basis of social science when considered it as only focused on the dichotomy nature vs. nurture. They also point on the overestimation of the importance of SSSM for the development of social science and intellectual life, as well as for creating the theoretical basis for secular ideology in modern society.

Nevertheless, despite the above criticism, the concept of Standard Social Science Model allows to more clearly fix the problem concerning different epistemological strategies for consideration of the human mind and behavior, as well as to see the effects that have such strategies in science and society.

State-Sanctioned Punishment as Deterrent to Violence

Criminal justice system; Norms and social contract; Punishment

Definition

State punishment is an administrative system of punishments which functions are deterrence, retribution, communication, incapacitation, or rehabilitation of criminal offenders.

Introduction

Aggression is any form of behavior that goals to harm or injure (Baron 1977), while the violence is an aggression that has extreme harm as its aim (Anderson and Bushman 2002). Aggression mechanisms have emerged as solutions to a host of distinct adaptive problems, such as retaliate against or punish group members who violate social and moral norms (Buss and Shackelford 1997; Durrant and Ward 2015). The social structural and cultural factors play a role in the nature and form of punishment and how these have changed over time (Durrant and Ward 2015). Punishment can be defined as the intentional infliction of sanctions by the state on who have unjustifiably harmed other people (Boonin 2008). In addition, Miller and Vidmar (1981) suggest that punishment is a negative sanction intentionally applied to someone who is perceived to have violated a law, a rule, a norm, or an expectation. From an evolutionary perspective, the ultimate function

of punishment is to communicate to group members or outside kin offenders the appropriate behavior according to the social norms and to deter these future aggressions from occurring (Durrant and Ward 2015). Punishment remains the central tool of dealing with normative violations and criminal offenders in modern societies.

State-Sanctioned Punishment

Criminal justice system, as an institution that provides the administration of punishment, can provide signals as to the normative boundaries of human social behavior. It also serves to put limits in the extent of offending acts (Carlsmith 2008; Durant and Ward 2015). Indeed, this tendency to punish who transgress social norms is arguably a universal feature of all human societies (Hoffman 2014). Changes in legal practices have an important role to play in the violence context (Durant and Ward 2015).

The mechanisms underlying punishment are related to altruistic and cooperative processes. Punishment's mechanisms are evolutionary adaptations that have been selected because of their enhanced biological fitness by sanctioning group members who violate the norms, promoting cooperative actions and cohesion of the group. Also, punishment increases the likelihood to communicate a model of appropriate behavior to the offender and to other members and express disapproval to a criminal conviction (Durant and Ward 2015).

According to criminal justice literature, punishment functions are deterrence, retribution, communication, incapacitation, or rehabilitation of criminal offenders. The type of punishment depends on the justice paradigm, but in general, the punishment for criminal offenders is the prison sentence that operationalizes the severity of the punishment in years of imprisonment. The legal system is responsible for protecting citizen interests and rights (Durrant and Ward 2015). A state-sanctioned punishment is increased by the power of centralized governments that remove the punishment from the hands of the aggrieved and place it instead in the hands of objective and neutral legal systems (McCullough 2008).

Conclusion

When the state legitimates the law and has the power to apply punitive sanctions with enough severity, violence tends to decrease (McCullough 2008). The states that are most efficient at controlling violence and retaliation are those that are effective at enforcing the law, protecting their citizens from harm, and punishing violators (McCullough 2008). State-sanction punishment should have the functions of protection and defense of citizens and punish norm violators. As the sociologist Norbert Elias (1969) wrote, “When a monopoly of force is formed, pacified social spaces are created which are normally free from acts of violence.”

State-Sanctioned Punishment as Substitute for Tribal Vengeance

[Punishment](#); [Retaliation](#); [Revenge](#)

Definition

State punishment is an administrative system of punishments that mediate conflicts between aggressors and victims and replaced the previous sanction of tribal revenge.

Introduction

Revenge is considered a taboo in modern societies, but blood revenge is one of the most commonly cited causes of violence and warfare in tribal societies (Chagnon 1988). Evolutionary psychology considers that revenge could be transmitted by primary mechanisms and by cultural transmission, assuming that revenge is a built-in feature of human nature (McCullough 2008).

The definition of revenge is similar to biologists' definition of punishment. Clutton-Brock and Parker (1995) define punishment as a costly imposition of costs that results in delayed benefits for the punisher. McCullough et al. (2013) claimed

that revenge is defined when the imposition of costs at a cost is only a response to an imposition of harm or a benefit-withholding that was caused by a mechanism designed to deter cost-impositions or benefit-withholdings in the future.

Evolution of Punishment

Tribal revenge can mean retaliatory killing, revenge raid on the members on the current community of the initial killer (Chagnon 1988). Using selection thinking, the propensity of revenge may have been selected because it helped to deter individuals who aggressed against ancestral humans from harming them a second time, to deter some would-be aggressors, and for punishing members of the social group who failed to pitch in to the common good (McCullough 2008).

“Evolution of Punishment,” by A. Warren Stearns (1936), helps to understand how this tribal vengeance was substituted by state-sanctioned punishments. Stearns assumes that in this early period, known as private vengeance, the fundamental purpose of punishment had to do with defense of private groups and family members, and the immediate motivation was an aggression or offense. In those tribal societies, every kin-based group had its codes and conventions based on vengeance (Blick 1988). But, these punishments could also engage the members in paybacks with no due process and without proportionality, causing the cycle of revenge (Stearns 1936; Walen 2016).

The development of complex codes of punishment and justice is concomitant with the beginnings of organized societies, e.g., Chinese and Hebrew people. This private justice period is marked by the governmental intervention to regulate the retaliation, protecting the individuals from excessive or unjust vengeance (Stearns 1936). The “eye for an eye, and tooth for a tooth” law was the beginning of a rising political state. Justice appeared as an abstract sanction that transferred the responsibility of punishment, previously belonging to the kin, to the state. Besides deterrence function, the punishment began to have a preventive function, following the idea that the more severe the punishment, the greater its effect (Stearns 1936).

Justice theories started to substantiate a deterrence and teaching purpose for the punishment, applying proportionality of punishment as the modern substitute for the primitive practice of private vengeance. The current state of public vengeance is arranged by the mediation of conflicts between offender and victim by the modern criminal justice system, establishing and measuring punishment (Walen 2016).

Revenge by individuals or extended kin groups was replaced by formal adjudication in societies with favorable resource bases and vertical inheritance (McCullough et al. 2013). According to Boonin (2008), punishment in the criminal justice system is intentional, directed toward a particular end, retributive, and harmful and expresses disapproval or censure, resulting in suffering or deprivation to the offender. State-sanctioned punishment follows a violation of important social norms that protect common interests of political community (Walen 2016).

Conclusion

The evolution of tribal vengeance to state-sanctioned punishment follows the development of societies as a complex political system (Walen 2016). The main purpose of revenge system is to deter an aggressor or would-be aggressors from imposing future costs to the victim (McCullough 2008; McCullough et al. 2013), whereas criminal justice system serves as an institution that administers punishment. Tribal vengeance punishment was applied in the victim-aggressor context within a close kin relationship and without clear rules of magnitude of punishment. State-sanctioned punishment is based on the socially built idea of justice as the mediator of the conflict, responsible for applying the punishment according to societal norms and the law (McCullough 2008; Roberts and Murray 2013). It is plausible to assume the individuals would stand to benefit from the social stability that comes from replacing revenge with other means of sanctioning as the punishment by the representatives of social institutions (McCullough 2008; Ward and Salmon 2009).

Social Ranking

Definition

A social structure in which some individuals have priority of access to resources relative to others.

Introduction

In most species (including humans), competition and cooperation among members of a social group produces a complex social structure called a **status (or dominance) hierarchy** in which some individuals have regular priority

Denise D. Cummins is retired.

of access to resources and fertile mates in competitive situations. These individuals are referred to as high status (or high ranking). Individuals who have lower priority of access are called subordinate or low status. In its most developed form, the dominance hierarchy is transitive, meaning that if A has priority over B and B has priority over C, then A has priority over C and so on.

Because of their privileged access to resources, higher-status individuals are less likely to die of predation or starvation and more likely to leave living offspring. Among species in which status is unstable, the level of reproductive success achieved by any individual is directly related to the length of time during which that individual is high ranking. Accordingly, there is a direct relationship between status and *inclusive fitness* (reproductive success of individuals and their closely related kin).

In small-scale human societies, men's social status is positively associated with various indices of reproductive success such as number of mates and surviving offspring (von Rueden 2014). In large-scale, modern human societies, status is highly correlated with potential fertility (as estimated from copulation frequency), accounting for as much as 62 % of the variance in this proximate component of fitness (Pérusse 1993). This value is comparable to that found in small-scale societies.

Types of Status Hierarchies

According to an influential model of hierarchical sociality, there are two systems of status – “two ways to the top” (Henrich and Gil-White 2001). In the **dominance** route, physical intimidation and coercive power are used to achieve high-status positions. In the **prestige** route, skills and knowledge translate into social influence and social status. Among species in which rank is unstable (as opposed to fixed and inherited), status in both types of hierarchy depends on individual differences in physical characteristics and social cognition acumen.

Physical Correlates of Status

Physical size. Physical size and rank are correlated in many species, with larger individuals tending to be higher ranking (Ellis 1995). Successful leaders in both small-scale and large-scale modern human societies tend to be taller than average and to possess more masculine facial and vocal characteristics (Mayew et al. 2013; Stulp et al. 2013).

Age. Adolescent chimpanzees are subordinate to all adult males, and status striving among males typically involves younger males challenging older ones. Rank declines with physical age, but alphas may maintain high-ranking positions through coalitions with other males.

In small-scale human societies, older adults typically fill leadership roles. This is primarily because they have had more time to accrue task-relevant knowledge and interpersonal skills and have larger adult kinship networks. During times of institutional change or informational obsolescence, however, younger individuals are more likely to hold leadership roles.

Gender. Female dominance over males is rare among mammals, being reliably observed only in hyenas, horses, bonobo chimpanzees (*Pan paniscus*), and certain species of monkeys, such as macaques and vervet monkeys.

Leadership positions in small-scale human societies typically are held by men. Women's opportunities tend to be limited by demands of caring for multiple dependent offspring, who spend more time as prereproductives than any other species. These caregiving demands limit opportunities for networking beyond the extended family.

Hormone-dependent social interaction styles. Status correlates with levels of sex hormones and cortisol in many species of primates, including humans. Higher testosterone levels are associated with higher social rank in nonhuman primate males and human males (Sherman et al. 2015). In female chimpanzees, higher levels of circulating estradiol are associated with higher status; in human females, it correlates positively with measures of implicit dominance motives (Stanton and Edelman 2009).

Eisenegger et al. (2011) provide detailed summaries of research on the relationship between testosterone levels and dominance or status behaviors. They report that salivary testosterone levels correlate with implicit measures of power motivation, increased vigilance for status threats, and high-risk tolerance. They also report that single-dose administration of testosterone reduces subconscious fear and fear-potentiated startle response, reduces trust in economic games, reduces cognitive empathy, and increases social cooperation.

Cortisol inhibits the impact of testosterone, and the interplay of these two hormones has been found to regulate status-related behaviors (Mehta and Josephs 2010): Across two studies of leadership and competitive behavior, testosterone was found to positively correlate with dominance, but only in individuals with low cortisol. In individuals with high cortisol, the relation between testosterone and dominance was blocked or reversed, particularly following social defeat. These findings suggest that high testosterone levels facilitate status attainment only when cortisol is low. When cortisol is high, the impact of testosterone is blunted.

These findings were replicated in a study based on 78 male executives (Sherman et al. 2016). Despite the myriad nonhormonal factors that determine organizational promotion, the executives' hierarchical position in their organizations could be accurately predicted from their endogenous testosterone and cortisol levels: Testosterone positively predicted executives' number of subordinates, but only among low-cortisol executives.

Numerous studies have also found that the relationship between hormone levels and status is bidirectional, that is, changes in status can have profound impact on testosterone, cortisol, and serotonin levels. Following contests of rank among nonhuman primates, defeated males exhibit a drop in testosterone levels, while winners' levels rises; serotonin levels rise in subordinates who improve their social status. Among humans, male winners typically show elevated testosterone levels relative to losers; this is true even when the competition involves little physical

action, as in chess competitions or contests in reaction time (see Eisenegger et al. 2011).

Compared to socially dominant individuals, subordinate or submissive individuals have higher baseline cortisol levels and display greater changes in physiological stress indices during conflict and slower recovery from conflict-induced changes in cardiovascular activity measures. The reason for this may lie in the diminished power lower-ranking individuals possess to control events in their everyday lives.

Social Skills, Reputation, and Social Capital

Among male primates, rank within the dominance hierarchy is acquired and maintained through dyadic aggression, and alliances determine the fate of outranked individuals. Importantly, these alliances are formed and maintained through cooperative effort or, more precisely, through the formation of reciprocal obligations. During agonistic encounters, individuals typically call for help, and *non-kin* allies are more likely to supply that help if the individual in question has groomed them, shared food with them, or assisted them in agonistic encounters in the past. Similarly, they punish noncooperators by directly aggressing against them when they themselves request help, failing to come to their aid, or by misinforming or failing to inform them about the location of food.

What counts as sufficient reciprocation also depends on rank. Among those close in rank, the rate of intervention by individual A on behalf of B is proportional to the rate of intervention of B on behalf of A. But high-ranking individuals need not to reciprocate as often as subordinates in order to maintain an alliance. The most frequent explanation given for this is that greater benefits derive from their interventions due to their priority of access to physical and social resources. Accordingly, nonhuman primates often focus their alliance-building efforts on higher-status individuals. For example, baboons, macaques, and vervet monkeys form matrilineal hierarchies in which any female is dominant to all the females

that are subordinate to her mother, and she is subordinate to all the females that are dominant to her mother (Cheney and Seyfarth 1990). During agonistic encounters, support is typically given to the higher-ranking females who in turn intervene in conflicts when they themselves are dominant to the target of the aggression. By aiding higher-ranking females, lower-ranking females form strong alliances based on reciprocal obligations that enable them to move up in rank.

In small-scale human societies, men with large kinship networks are more likely to gain political influence, but social support from non-kin is also instrumental in the acquisition and maintenance of status (see von Rueden 2014). Among Tsimane men, influence within small groups and at the level of the community depends on social support from non-kin as well as kin, and the formation of such alliances depends on cooperation through activities such as food sharing. To express commitment to food sharing, some societies, such as the Ache of Paraguay and Hadza of Tanzania, consider it taboo for hunters to consume portions of their own kills or to brag about their hunting prowess. Instead, successful hunters are expected to deprecate their own achievements and to share meat generously. Doing so not only facilitates alliance formation but signals quality as a mating partner.

Henrich et al. (2005) conducted a cross-cultural study on social decision-making involving 15 small-scale horticultural, foraging, and pastoral cultures in Africa, South America, and Asia. The tasks involved economic games in which participants are given an opportunity to cooperate with or exploit others in economic transactions. A cornerstone of economic theory is that rational agents are self-interested, that is, when making choices about allocations of resources, rational agents make choices that maximize benefits to themselves. But that is not what the researchers found. The rational self-interest model failed to a large degree in all of the societies. For example, in the ultimatum game, one party proposes how to divide a resource (proposer), and the other party is allowed to accept or reject the offer (responder). If the offer is accepted, the resource is divided as agreed. If the offer is rejected, no one gets anything. Many

ultimatum proposers among the Au and Gnao of Papua New Guinea offered their partners more than half, but they were frequently rejected. The authors interpreted this pattern of behavior as a reflection of status seeking through gift giving, which is common throughout Melanesia. In these societies, accepting gifts implies a strong obligation to reciprocate, and reciprocation often takes the form of political alliances.

More than a decade of research in large-scale industrialized societies has also challenged the legitimacy of the “rational agent” model as a descriptive model of human behavior. People do not always seek outcomes that maximize benefits for themselves. Instead, our choices appear to be equally motivated by concerns about fairness, equity, and reciprocity. The modal response in studies based on economic games is to trust with the expectation of reciprocity, and failures to reciprocate are met with retaliation in subsequent games. In fact, players and observers are willing to pay a penalty for the opportunity to punish nonreciprocators (Fehr and Fischbacher 2004). In order to accommodate these results, normative theories have been proposed in which reciprocity, altruism/spite, and inequity aversion play prominent roles. When viewed from these theoretical perspectives, individuals enter economic transactions with normative standards of fairness, and their decisions are guided in large part by distance from the expected normative division. Behavior that departs significantly from these norms elicits retaliatory, spiteful, or other apparently “irrational” response profiles that depart significantly from predictions based on simple self-interest.

Even here, however, the impact of relative status looms large, as does the way in which status is achieved. When the role of proposer is awarded arbitrarily, proposers behave fairly toward their transactional partners (offering close to 50 %), and responders typically reject unfair offers. But when told transactional roles have been assigned on the basis of performance on competitive outcome (e.g., score on a trivia test), exploitation becomes the modal response: High-ranking individuals offer their low-ranking partners less and low-ranking responders are willing to accept less (Hoffman et al. 1996).

When status is awarded on the basis of prestige, however, high-ranking individuals behave more generously toward low-ranking transactional partners, a norm referred to as *noblesse oblige*. Fiddick et al. (2013) investigated tolerance toward nonreciprocation in participants from seven countries that vary along hierarchical and individualist/collectivist social dimensions. They found strong and converging evidence of *noblesse oblige* in all seven countries. Compared with participants who adopted an employee perspective, those who adopted a boss perspective were far more willing to continue a reciprocal arrangement despite significant noncompliance, were more likely to feel they had been treated fairly, felt less animosity toward their cheating partners, and believed they got the better deal because they felt they bore less cost and received higher value from the arrangement. These results obtain even when the employee was described as having higher income than the boss (due to sales commissions) (Fiddick and Cummins 2007). The authors interpret this pattern of results to mean that *noblesse oblige* is a cross-cultural norm whose function is to honestly signal phenotypic quality through costly displays which enhance reproductive success, successful alliance formation, and enhanced feelings of internal satisfaction (utility). Alternately, high-status individuals might be more altruistic not because of costly signaling but because their reputations are more easily damaged owing to more intensive scrutiny.

Social Cognition and Status Acquisition

Status hierarchies are rarely static structures. They are instead dynamic structures in which individuals vie for control of resources. Higher-ranking individuals defend their privileged access to resources by detecting and punishing acts that threaten privileged access, while lower-ranking individuals attempt to engage in forbidden activities in order to secure a larger share of resources. In order to survive, an individual must be capable of performing – on a nearly continual basis – the following cognitive tasks: (a) making rank and kinship discriminations, (b) recognizing what is

forbidden and what is permitted based on one's rank (social norm cognition), and (c) deciding whether to engage in or refrain from activities (reciprocity, “mind reading”) that will allow one to move up in rank (i.e., garner a larger share of resources). These are the reasoning problems that impact most directly on survival and reproductive success.

Investigations of social interactions in a variety of species (including humans) have found that those who achieve high status are those who are particularly adept at these types of social cognition. In other words, *selection favors those who have social and political intelligence*.

Rank discrimination. Nonhuman primates readily make kinship and rank discriminations among individuals in their social groups, a skill that depends on transitive reasoning when all possible dyadic interactions are not directly witnessed (Cheney and Seyfarth 1990, pp. 91–96). (They infer that A is dominant to C given that they have witnessed interactions in which A is dominant to B and B is dominant to C.) In contrast, they can perform transitive inference on object-oriented tasks only after considerable drilling with paired stimuli (Gillan 1981).

Human infants as young as 10 months of age can infer dominance hierarchies from observing interactions between similarly sized actors (Gazes et al. 2015). Status hierarchies are apparent in the play groups of preschool children as young as 2 years of age (Strayer and Trudel 1984), and the transitive relations can be reliably reported verbally by 4-year-olds. Yet, like other primates, children can perform object-based transitive reasoning only if they are extensively drilled on the object pairs upon which the inference is to be performed. Truly content-free transitive reasoning does not reliably appear until 6 years of age. As early as 3 years of age, preschoolers are able to infer dominance not only from physical supremacy but also from decision power, age, and resources (Charafeddine et al. (2015)). They also have expectations regarding the ways in which a dominant and a subordinate individual are likely to differ in that they expect an individual who imposes his choice on another to exhibit higher competence in games and to have more resources.

Children also prefer to associate with and imitate high status as opposed to low-status individuals.

Santamaria-Garcia et al. (2015) combined event-related potentials (ERP) and structural magnetic resonance imaging (MRI) to reveal the neuroanatomical substrates of early status recognition. Participants performed a task either with a superior or with an inferior player. The pattern of ERP and imaging results indicated early recognition of social hierarchies through activation of a network involved in the automatic recognition of social identity.

These results indicate that rank discrimination cognition emerges early in development and functions fluidly as an automatic cognitive process through adulthood.

Social norms. From a cognitive standpoint, a social hierarchy is, essentially, *a set of social norms that constrain the behavior of individuals depending on their rank* (Cummins 1998). Norms are socially constructed objects that are created by agents to direct the behavior of other agents over whom they have authority. They prescribe constraints on social behavior that dictate what is permitted and obligated. An agent succeeds in creating a norm depending on whether the agent has the authority to do so.

In animal societies, these “social norms” are implicit yet reflected in virtually every activity, including who is allowed to sit next to, play with, share food with, groom, or mate with whom. In order to avoid punishment (or ostracism, which can mean death due to predation or starvation), individuals must learn what is *permitted*, what is *forbidden*, and what is *obligated given their place in the hierarchy*. High-ranking individuals monitor the behavior of subordinates in order to protect their privileged access to resources. High-status individuals typically take on the role of enforcing these implicit “social norms,” aggressing against those who violate them and breaking up disputes between lower-ranking individuals (Boehm 1999).

All human societies depend on social norms to regulate daily interactions. These norms may be implicit or explicitly codified as regulations or laws. Social norm reasoning has been found to emerge early in human cognitive development;

very young children show a marked *precocity* for acquiring social rules and monitoring compliance with them (see Cummins 2013). Children as young as 3 years of age do not just follow social norms; they actively enforce them on others – even when serving as spectators rather than players in the game. They do not need to be explicitly instructed about the rules by an authority, but they do need to see that an authority expects such behavior. When asked to test compliance with social rules, 3-year-olds also spontaneously seek out potential rule violations, readily distinguish rule-violating behavior from compliant behavior, and provide cogent explanations as to why violating instances constitute violations of the rule. In fact, their performance is equivalent to adults on these social reasoning tasks. In contrast, when asked to perform a nonsocial task of apparent equal complexity (test the truth of a rule rather than monitor compliance), children and adults fail to seek out potentially falsifying evidence, often fail to distinguish confirming from falsifying instances, and cannot give coherent justifications for their decisions.

These studies indicate that the average 3-year-old has as firm a grasp on the implications of socially prescriptive rules as the average adult, while the average adult fails to grasp the normative rules for testing the truth of rules or hypotheses.

Mind reading. Unlike objects, agents move of their own volition and are motivated by internal states that are not directly perceivable by others. As a result, successful cooperation and competition frequently depends on forecasting the behavior of others, a skill referred to as “mind reading” by the ethologists. In psychology, the term “theory of mind” is used to refer to the ability to not only forecast behavior but to attribute mental states (beliefs, intents, desires, knowledge) to oneself and others and to understand that others have beliefs, desires, intentions, and perspectives that are different from one’s own.

A singular cognitive skill that relies on mental attribution is **deception**. A successful deception creates a false belief in the one deceived. Subordinates in primate hierarchies engage in deceptive behavior that improves their access to

resources (Byrne 1995). For example, they conceal objects or behaviors from others by hiding them from view, acting quietly so as not to attract attention, avoiding looking at desirable objects themselves, or distracting attention away from the desired object or forbidden behaviors. This behavior allows subordinates to garner a larger share of resources immediately or to increase the probability of future rewards if the deception involves surreptitious food sharing or grooming to form alliances that can be called upon during contests of rank.

The neocortex ratio expresses the relative volume of the neocortex compared to the volume of the rest of the brain. It correlates with the mean group sizes that characterize primate species, with larger group sizes corresponding to greater neocortical volume. This ratio correlates with the prevalence of tactical deception observed across primate species (Byrne 1995, pp. 219–221). Not surprisingly, species that show the greatest capacity for this type of deception (such as common chimpanzees) also have the most unstable hierarchies. Greater cognitive skill mitigates the impact of physical size and strength in dominance acquisition and maintenance. It is difficult to physically dominate individuals who have the cognitive wherewithal to outwit you and to form stealth alliances with others. In order to dominate such individuals, one must have the cognitive wherewithal to recognize and thwart acts of deception whose target is flouting norms concerning privileged access to resources.

The manner in which mind reading is successfully deployed to acquire and maintain status depends on the size of the social group; the larger the group, the more likely deception will succeed. For example, the ability to persuade through oratory is typically requisite for gaining political influence within small-scale societies, even those that seemingly lack formal authority, such as the !Kung and the Semai of Malaysia. But in such societies, trustworthiness, generosity, and fairness are integral to leader emergence and effectiveness (von Rueden et al. 2014). Accordingly, most have developed norms and traditions regarding leadership that depend on demonstrating these qualities, thereby protecting members against exploitation

by leaders. For example, although hunting prowess is a ubiquitous determiner of male social status in human small-scale societies, meat-sharing generosity determines coalitional support and hence stability of political leadership (von Rueden et al. 2014). Generosity must be carefully deployed to signal less about their wealth and more about its use to benefit the community. This usually means that generosity must be combined with obvious signs of humility to avoid sewing distrust rather than affiliation.

As Boehm (1999) observes, the egalitarianism of small-scale societies is often misconstrued as an absence of dominance motivations (or status striving) on the part of group members. Yet, as von Rueden and van Vugt (2015) point out, leaders in these societies may orchestrate collective actions that produce goods more beneficial to themselves and their kin. For example, wealthy Barabaig pastoralists enforce conservation of grazing land because their larger herds stand to benefit the most. They may also claim a fee for their services through a greater share of normatively regulated benefits (e.g., rights to polygyny). Instead, small-scale society egalitarianism is better understood as an active leveling of would-be dominants through norms compelling humility and coordinated punishment of aggrandizers (Boehm 1999). In short, leaders must carefully manage perceptions of their generosity and fairness or risk censure, ostracism, or even execution.

While small-scale human societies frequently institute norms that proscribe deceptive exploitation, modern large-scale societies frequently fall prey to (and even reward) such behavior. For example, the GLOBE surveys on leadership in 62 modern large-scale societies show that integrity is a universally highly valued leader trait (Den Hartog et al. 1999). Yet in these societies, individuals who are perceived and rated as socially dominant are better at deceiving others, persuading others, and interpreting others' intentions. von Rueden and van Vugt (2015) present a comprehensive review of research on large-scale industrial societies which indicates that individuals who are narcissistic or overconfident are often selected as leaders despite null or even negative consequences for groups. They point out that in these

contexts, overconfident and narcissistic leaders are often mistaken for competent and agreeable leaders because they are persuasive, charming, and sociable. Deceptive traits associated with psychopathy may be socially adaptive in the short run in large populations of altruistic and trusting individuals.

Sex Differences in Status Striving

Among mammals, females necessarily invest more energy in reproduction than do males (e.g., pregnancy and lactation), and females are typically more involved in the care of very young offspring (i.e., infants and toddlers). Comparatively speaking, therefore, female reproduction is limited by access to resources, while male reproduction is limited by access to mates. Female lifelong reproductive success is enhanced by investing in offspring to ensure their survival. For this reason, women traditionally have competed for high-status men who typically control more resources. For example, women in polygynous societies that restrict the avenues women may pursue to obtain resources typically prefer to be one of the many co-wives of a prosperous man than the only wife of a poor one. In western cultures that have legally enforced monogamy and relatively greater financial opportunities available to women, high-status men are nonetheless still preferred as mates and as partners in extramarital affairs (Pérusse 1993).

Intrasexual competition among females has received less attention from researchers than has intrasexual competition among males. This seems partly due to the fact that females compete in far subtler ways than do males. Males tend to use direct confrontation to dominate and subdue potential threats and rivals, while females prefer to use indirect means that can easily go undetected, such as spreading rumors aimed at ruining a potential rival's reputation, excluding, ignoring, and isolating her socially. A 2014 study conducted by the Workplace Bullying Institute found that 30 % of office bullies were women, and these female bullies targeted other women more than two-thirds of the time using indirect

means of aggression. Fisher (2015) proposed that females often prefer low-risk competitive strategies because they typically are the primary caregivers and protectors of offspring.

These sex differences in competitive strategies appear to be rooted in a social proscription against direct and overt female displays of dominance. Such displays diminish women's likability while enhancing men's likability and negatively impact outcomes such as hirability (Williams and Tiedens 2016). Implicit forms of dominance (e.g., eye contact), however, do not negatively impact these factors for females. The authors point out that the effect of dominance on men's and women's perceived competence did not differ, which indicated that these subjective social evaluations obstruct women from adopting leadership roles. In other words, women must seek to dominate rivals without appearing to do so.

These sex differences seem to be facultative rather than obligate in that they are significantly impacted by environmental contingencies. Gneezy et al. (2008) compared female competitive strategies in two distinct societies: the patriarchal Maasai of Tanzania and the matrilineal Khasi of India. Maasai men were apt to compete at roughly twice the rate as Maasai women, but this result was reversed among the Khasi, where women chose the competitive environment more often than Khasi men and even chose to compete more often than Maasai men did in their culture.

Cross-cultural sex differences exist for basic human values relevant to status striving. Men attribute more importance than women do to self-interested values such as power, achievement, and self-direction values, while women attribute more importance than men to other-regarding values such as benevolence and universalism. Power values pertain to the attainment and protection of status, prestige, and dominance over people and resources. Achievement values pertain to personal success through demonstrating competence according to social standards. In contrast, benevolence values motivate people to preserve and enhance the welfare of close others (e.g., offspring and other kin), while universalism values have as their goal promoting the welfare

of all people and for nature. But a reexamination of these factors conducted by Schwartz and Rubel-Lifschitz (2009) indicated that in societies with greater gender equality, both men and women attributed more importance to benevolence, universalism, and self-direction. Increased individual resources of wealth, education, and autonomy that accompany greater gender equality facilitate the expression and attainment of these values.

Conclusion

Status hierarchies are ubiquitous in the societies of human and nonhuman animals. These hierarchies constitute social norms that constrain behavior of individuals depending on their rank, dictating what is permitted or obligated in social interactions. They emerge as a result of individual differences in traits that impact access to resources, with higher-ranking individuals gaining priority of access to resources in competitive situations. Some of these traits that contribute to status acquisition and maintenance are physical in nature, such as size, age, and gender. Others pertain to social skills and cognition, such as skill at forming alliances based on reciprocal obligations, persuasion through oratory, or manipulation of beliefs through deception.

Definition

This chapter reviews work on the extent to which individual status influences support for the redistribution of scarce resources.

Introduction

Evolution by natural selection depends on competition over scarce resources. Within social groups, however, overt competition or hostility can be costly and ultimately a detriment to the well-being of group members. Accordingly, many primate species have evolved means of minimizing social conflict by imposing simple systems of dominance that determine access to and control over scarce resources. It is to these basic systems of distribution that many psychologists trace systems of status and distribution in human cultures, even if the rules and systems that shape outcomes are comparatively complex.

The present chapter briefly summarizes research on status, reflecting differences in access to and control over resources, and the redistribution of resources. This review highlights that status relations afford a degree of stability that can minimize intragroup conflict, but across species we see that status itself can sometimes motivate conflict by disadvantaged group members seeking to rework the current distribution of outcomes.

Status and Distribution

Status is an evolved means of minimizing competition over scarce resources within members of a species. Rather than needlessly expending effort in constant conflict, status creates implicit social rules regarding which members have control over resources and which do not.

These hierarchical relations are well studied in the context of primate behavior (for a review, see Kappeler and van Schaik 2002). Among many primate species, dominant males typically have greater control over scarce resources, including mates. Accordingly studies consistently find that higher-ranking primates have greater access to mates (Jack and Fedigan 2006; Wroblewski et al. 2009) and that male social rank is therefore a predictor of reproductive success (Gerloff et al. 1999; Widdig et al. 2004).

There is also evidence that female chimpanzees institute their own systems of dominance to control access to prime foraging areas. Dominant females therefore benefit from status because of the direct effects of improved nutrition for reproductive success, including greater infant survival and the production of more offspring (Pusey et al. 1997).

Beyond evidence of status hierarchy in primate societies, there is consistent evidence that status is a motivating factor in human social behavior. Across cultures, people desire status, even if this pursuit has been found to be stronger for males than females (Huberman et al. 2004). Other research has found that males are more sensitive to potential status differentials between themselves and other males (Gutierrez et al. 1999). This sex

difference may be attributable to the fact that human females are more likely to use male status as a marker of mate attractiveness (e.g., Kenrick et al. 1994).

These facts suggest that having status is ultimately adaptive for both the individual and the group. For the individual, the possession of status secures access to resources. While this reality creates disadvantaged group members, status relations provide groups with a degree of stability from which to maintain cooperation without the specter of unending overt competition between dominant and subordinate members. In other words, status creates a stable system for distributing scarce resources without constant conflict.

Status and Redistribution

This is not to say that status relations, or their consequences for the distribution of resources, are immutable. For example, among primate species, subordinate males often form coalitions against the status quo of their group (de Waal 2007). These coalitions allow subordinate males to reclaim a greater share of mates or other scarce resources from dominant group members (Wrangham and Peterson 1996). In these and other cases, coalitions allow members to pursue group-based interests: In some cases, subordinates benefit from upending status relations currently to their disadvantage; in others, dominant members come together to secure their position within a status hierarchy. The remainder of this chapter reviews research and theory about the evolutionary origins of processes related to this motive to seek (or prevent) redistribution on the part of social group members.

Social Dominance

Research on redistribution from an evolutionary perspective often adopts the view that individuals evolved to pursue group-based interests, that is, to achieve and maintain social dominance of other groups (Sidanius and Kurzban 2013; Sidanius and

Pratto 1999). This kind of behavior is well noted in close primate relatives, including research showing that coalitions form to pursue group interests, such as killing out-group males who are rivals for scarce resources (Wrangham 1999).

Social dominance motives have been noted in humans as well and are important individual predictors of attitudes toward resource redistribution. For example, dominant (White) group members who express high trait social dominance orientation tend to be resistant to any effort to upset the economic status quo, even if that hierarchy is not seen as legitimate (Levin et al. 2002). More socially dominant individuals also tend to be less supportive of social policies that ameliorate hierarchy in society, including unemployment benefits and public health care (Pratto et al. 1994).

If this motive to promote group-based interests is evolved, it would be expected that humans are highly sensitive to cues indicating a target's coalitional status as either a potential collaborator or competitor. Although race is a common line along which social group boundaries are drawn, research shows that individuals encode information about coalitional affiliation more strongly than race when there are clear group cues (Kurzban et al. 2001). This research promotes the idea that race and other salient group categories are of secondary importance to coalitional status and indeed may be relied upon primarily as heuristic judgments to assess the extent to which others may be expected to cooperate in the promotion of group interests.

Strategies for (Re)distribution

Other research has explored how evolutionary processes may have shaped the strategies that subordinate (vs. dominant) group members use to promote (vs. prevent) redistribution of resources. For example, group-based competition over scarce resources sometimes requires a degree of cooperation among in-group members. This cooperation is sometimes secured through social exchange: In one comprehensive review of food sharing behavior (Jaeggi and van Schaik 2011), the authors find evidence that many primate species share food among adults and that this food sharing behavior

is particularly likely among species that form coalitions. While food sharing with kin (e.g., offspring) is common in most primate species, exchange between adults is most likely when there are opportunities to attract mates with exchange or when food can be given to garner coalitional support to challenge (or preserve) status relations.

This research suggests that direct redistribution of resources to disadvantaged group members may be an evolved strategy for self-promotion to the extent that redistribution builds a coalition. Humans similarly balance prosocial motives with self-promotion to navigate status hierarchies. Research on status in children finds that those best able to garner and maintain status enact a combination of both coercive and prosocial strategies (Hawley 2003a, b). This dual focus allows individuals to both directly promote self-interest and at the same time mitigate the social costs of purely coercive or dominant social strategies through prosocial gestures.

How do individuals balance these self-promoting and prosocial strategies to effectively gain status and resources? Prior research finds that resource competition can trigger cooperation-seeking strategies but only when individuals lack the ability to compete on their own. This pattern has been found with male chimpanzees, for whom the probability of forming a coalition to protect access to mates was directly proportional to an individual chimpanzee's control over female mates (Watts 1998). As males lost control over access to mates, they formed increasingly powerful coalitions to restore shared dominance.

Other research has replicated this pattern in humans, showing that the use of competitive or cooperative strategies depends primarily on individual competitiveness (Benenson et al. 2009). In one study, individuals played a decision-making game in which they ostensibly played with a partner and a competitor. Each player was assigned a strength (i.e., a probability of winning a round) and given the option of playing the game alone, with the partner who would take a percentage of their winnings, or they could accept a guaranteed lesser payout. As an individual's strength in the game, that is, the probability of winning a round, increased, so did the percentage of individuals

opting for the competitive strategy. In contrast, as individual strength decreased, there was a marked preference for coalition formation.

Other research supports this view using measures of individual social status (Brown-Iannuzzi et al. 2015). Specifically, those who are wealthier are less likely to support policies that redistribute wealth, including spending on social programs. These effects were observed even on merely subjective differences in wealth: That is, merely feeling richer caused people to be less supportive of wealth redistribution.

Other research finds that strength, reflected by measured muscle mass, interacts with male status to shape support for redistribution (Petersen et al. 2013). The researchers assessed strength with a measure of bicep circumference and found that among lower-status men, physical strength was highly predictive of support for redistribution. In contrast, among higher-status men, this relationship reversed with stronger men expressing greater hostility toward redistributive policies. Notably, these findings replicated across three cultures (the USA, Denmark, Argentina), suggesting that they are unlikely to be due merely to cultural factors.

The latter findings suggest that individual competitiveness motivates individuals to support redistributive policies in their interest, while those who are less competitive are more willing to tolerate the status quo. The researchers note that this finding supports the asymmetric war of attrition model (Hammerstein and Parker 1982) in which those with the means to fight for access to resources should be willing to pursue conflict, while those without will cede resources to fight another day.

Not all attempts to seek redistribution are based on overt conflict however. Other research has considered the use of deception as a means of balancing the social scales. Recent research with chimpanzees finds, for example, that subordinates are aware of what a dominant member knows about the location of food and that they use this information to their advantage (Hare et al. 2000; Tomasello et al. 2003). Specifically, when subordinates saw food that was hidden from a dominant chimpanzee's line of sight, they pursued this food rather than attempting a direct challenge over food known to both parties. Importantly, this

preference was not observed when the subordinate saw that the dominant member witnessed the placement of this hidden food.

Criticism of Evolutionary Perspectives on Status and Redistribution

One popular criticism of evolutionary perspectives on status and redistribution is as follows: If the motive for social dominance is innate, then social dominance and intergroup conflict seem to be a biological inevitability (Turner and Reynolds 2003). After all, if conflict over status disparity is instinctive, some see the implication that equality is impossible and efforts at intergroup harmony as misguided. Other criticisms of social dominance approaches stem from the perceived assumption that group members primarily pursue their self-interests given that status is adaptive for group members (Jost et al. 2004). In other words, some see social dominance approaches as implying that group members will primarily pursue self-interest, despite evidence that subordinate group members sometimes legitimize social systems that work to their disadvantage.

In defense of an evolutionary approach to understanding status and redistribution, Sidanius et al. (2004) note that evolved tendencies must be considered subject to modification and variation in light of environment. In short, whatever evolved motives exist that incline individuals to pursue status or to upset hierarchy in the pursuit of self-interest must pass through the filter of current social pressures and cultural rules. This can create situations in which social groups support distributive policies against their own interests if, for example, there are cultural ideologies or political systems that override biological dispositions.

Conclusion

This chapter has reviewed evolutionary psychological theory and research on status and redistribution. In broad strokes, this research finds that status is an evolved mechanism that minimizes conflict in social groups and that affords

individual members specific advantages. However, status relations are often fluid, and research finds consistent evidence for evolved strategies aimed at either challenging or preserving the disparities inherent in status relations.

This research often takes the assumption that humans have evolved a motive for social dominance which motivates them to pursue the interests of themselves and their groups. Broadly this work finds that some individuals pursue (vs. prevent) redistribution by adopting competitive strategies, particularly when they are most able to challenge (vs. defend) the status quo. Other strategies include the use of deception to gain comparative advantages over high-status members or the formation of coalitions that can upset status relations. This work points to an important role of evolutionary processes in the psychology of status and redistribution, even if these phenomena ultimately involve factors that may moderate the expression of evolved traits.

Status and Reproductive Success

James G. Zerbe

Department of Anthropology, School of Human Evolution and Social Change, Institute of Human Origins, Arizona State University, Tempe, AZ, USA

Synonyms

Male-male competition; Reproductive skew; Social rank and fitness; Status competition

Definition

The common statistical association between accessing greater positions of relative social rank within a group and measures of evolutionary fitness.

Introduction

Social status seems to be a key component of social organization among small-scale human societies. Status is often defined as relative access to contested resources within a social group (Henrich and Gil-White 2001). More broadly, it can be conceptualized as access to social power and influence or the ability to advance one's aims and interests when they conflict with the goals or motives of others. The purpose of this entry is to provide a general introduction to the concept of social status and detailed results from research studies among two small-scale societies on the link between status and reproductive success, as well as citing summarizing research which provides context on the prevalence of finding this association when investigated.

Status and Reproductive Success in Small-Scale Societies

Even among the most egalitarian extant hunter-gatherer societies, relative status differences can be found in contexts of situational leadership. These instances illustrate the concept of prestige-based status, whereby individuals freely confer individuals, often in the role of leaders, with their influence because they possess knowledge, skills, or experience that assist leaders in coordination of group-beneficial collective action (Henrich and Gil-White 2001; Hooper et al. 2010). A key distinction exists between status that is derived from prestige with status which is derived from dominance. In contrast to prestige, dominance is status or deference given by subordinates to avoid physical costs during interactions with a dominant individual (Henrich and Gil-White 2001).

Research conducted among small-scale societies provides empirical support for the link

between accessing social status and increasing proximate measures of reproductive success. Among the Tsimane forager-horticulturalists of the Bolivian Amazon, high-status men were discovered to enhance their fitness via multiple pathways (von Rueden et al. 2011). Both prestigious and dominant men were found to possess more allies and have higher fertility, more extramarital affairs, more attractive wives, and a higher probability of remarrying if divorced or widowed (von Rueden et al. 2011). However, there were some differences in how prestigious and dominant men were achieving higher relative fitness. Prestigious men were found to have offspring with lower childhood mortality, marry at earlier ages, and have wives who begin reproducing at earlier ages, while dominant men did not. However, dominant men were found to marry younger women and have wives who spend more time caring for offspring, while prestigious men did not (von Rueden et al. 2011). Another well-known case is that of Yanomamo who can acquire the special signifier and cultural status of *unokai*. *Unokai* are men who have been recognized as having gone on a raid against another village and killed an enemy. In comparison with non-*unokai* men, *unokai* were found to have approximately twice as many wives and three times as many children (Chagnon 1988). This research has long been controversial and contested, but a recent reanalysis with a more informed statistical model and proper controls replicates the original finding (Macfarlan 2015). Specifically, *unokai* are enhancing their relative fitness by engaging in a system of marriage exchange with their co-*unokai*, i.e., men who participate in raids together. Nearly half of all co-*unokai* dyads married women from each other's patriline, providing a mechanism to explain the finding that they have more wives and therefore children than men, non-*unokai*, who don't participate in this large system of raiding and wife exchange (Macfarlan et al. 2014).

The Tsimane and Yanomamo are just two cases which support a link between status and reproductive success. Elsewhere, von Rueden has summarized a near exhaustive list of relevant data which tests this association in small-scale societies (2014).

He notes that 71% of studies that tested for it found a relationship between higher status and more surviving offspring, while 78% of studies that tested for it found a relationship between higher status and greater fertility and that 67% of relevant studies detected an association between higher status and lower offspring mortality (von Rueden 2014). The association between social rank or status and reproductive success characterizes male primates generally, including humans in small-scale societies (von Rueden and Jaeggi 2016). Interestingly the strength of the association between higher status and higher fitness is broadly consistent across foraging, horticultural, pastoralist, and agricultural societies (von Rueden and Jaeggi 2016).

Conclusion

Taken together, this empirical evidence supports the notion that there exists in human psychology an evolved desire or taste for achieving heightened social status since in small-scale social contexts it is reliably predictive of fitness enhancing outcomes.

Definition

Status is defined as an individual's relative access to contested resources in a group (Henrich & Gil-White, 2001). Status can be more broadly

conceptualized as an individual's influence in pursuing their interests and goals when they conflict with the motivations and interests of others. Status competition is comprised of all the behaviors and strategies which individuals use as they vie for more relative influence and status.

Introduction

Potential status differentials among individuals are an important aspect of political dynamics in small-scale societies generally. This entry will present the evolutionary logic underpinning status competition, its general relevance to human evolution and social organization, and empirical studies on its overt expression in small-scale societies.

Status differences are considered a near human universal, that is, it occurs in some form, degree, and context in almost every society known ethnographically (von Rueden 2014). Acquiring status appears to be a viable strategy for achieving enhanced reproductive success assuming that when individuals have greater ability to pursue their interests, they make decisions that have fitness enhancing effects. This assumption is supported by an interspecific and cross-cultural analysis that greater status is associated with enhanced individual reproductive success in men and male nonhuman primates (von Rueden and Jaeggi 2016). This relationship is consistent in degree for humans across forager, horticulturalist, agriculturalist, and pastoralist societies (von Rueden and Jaeggi 2016). This general importance of status in achieving reproductive success therefore sets up the competitive contexts in which individuals strive to acquire status.

Status competition has been an important influence on human evolution. While human sexual dimorphism is notably reduced relative to older hominin species, indicating less dyadic male-male competition for mate access, our evolved system of status competition importantly involves alliance building that attenuates how social power is distributed (Boehm 1999). This is the case even among the most assertively egalitarian mobile foraging societies. Christopher Boehm notes that group-wide coalitions are a social mechanism that

guards against authoritarian social behaviors among individuals in a band (1999). This in and of itself is an example of status competition. Any incipient authoritarian individual who strived to acquire disproportionate social power over others were often killed in response in order to deny them the social power they tried to wield. Status competition should therefore be recognized as occurring even if allies form bottom-up revolutionary coalitions to maintain an approximately egalitarian distribution of social power (Boehm 1999). However, these dynamics and tendencies do importantly become altered in other types of small-scale social organization where status striving is less constrained and guarded against than in egalitarian foragers. The next paragraph presents some empirical data regarding status competition in several of these types of small-scale contexts.

As noted, alliances between individuals drastically attenuate the importance of body size and formidability in dyadic male-male competition. That is, it is unlikely that one individual can successfully compete against two individuals who are in alliance and support one another in a coalition. The importance of alliances and coalitional support in acquiring status is supported by several studies. Among Tsimane hunter-horticulturalists, men who have greater social support via central positions in kinship networks and more allies achieve greater reputations for various forms of status, such as perceived ability to win in a dyadic fight, getting their way in a group context, community-wide influence, and overall respect (von Rueden et al. 2008). This acquisition of status among the Tsimane is also a fitness enhancing strategy (von Rueden et al. 2011). Prestigious and dominant Tsimane men were found to have more allies and were observed to have higher fertility, more extra-marital affairs, more attractive wives, and more likely to remarry if divorced or widowed (von Rueden et al. 2011).

Yanomamö men have been found to strive to acquire the culturally significant status of *unokai*. A man becomes an *unokai* when he is recognized as participating in a raid against an enemy village and successfully kills someone (Chagnon 1988). Being an *unokai* has notable fitness enhancing effects; compared to non-*unokai*, *unokai* have twice as many wives and three times as many

children (Chagnon 1988). Importantly, these effects remain robust when a more sophisticated analysis with proper controls for confounding variables is used (Macfarlan 2015). More recent research has revealed how men achieve enhanced fitness via alliance building by co-participation in raids. Among all co-*unokai*, men who participated and killed during a raid together, nearly half eventually engaged in some type of marriage exchange of women from each other's patriline (Macfarlan et al. 2014), which provides the mechanism by which *unokai* acquire more wives than non-*unokai* (Chagnon 1988).

Similar patterns are observed among other Amazonian hunter-horticultural groups, such as the co-residing Achuar and Quichua of Conambo, Ecuador. Patton shows that men strive for status by developing reputations as willing and capable warriors (2000). Importantly, the association between warriorship and status is mediated by coalitional membership; individuals allocate social status to reputable warriors from their own but not the opposing political coalition in Conambo (Patton 2000). This relationship can also be shown at the level of dyadic alliances; men are biased to give more status to men of their own coalition with which they are more strongly allied (Patton 2005). These results support that men strive and compete for status allocated by other coalition members and allies by engaging in coalitional conflict on their behalf. And in this particular context of Conambo, having more status than similarly aged men was found to be associated with women's perceptions of male attractiveness (Escasa et al. 2010). While, developing a heightened reputation of warriorship is associated with being considered a better potential son-in-law by other men (Patton 2005). These studies present data on quite overt forms of status competition, but status striving also takes nonviolent forms involving more nuanced dynamics of reputation formation, cooperation, and relationship formation.

Conclusion

Social status is indicative of a greater ability to pursue one's interests. The persistent link between greater social status and measures of fitness

therefore support the evolutionary and adaptive basis of status striving. Further, ethnographic case studies support that status acquisition is affected by and occurs in political contexts of alliance building and coalitional competition.

Definition

Status competition is the contest or rivalry between two or more individuals over the pursuit of influence, deference, attention, and associated resources. Peer relationships are associations between two or more individuals that may vary in closeness and duration and which reflect and sometimes lead to the creation of friendships, partnerships, allegiances, and group membership.

Introduction

While the underlying fabric and structures of human groups are diverse, two processes seem

ubiquitous to social life: individuals desire affiliation with others and form social hierarchies. From the formal social organization of businesses to the relationships within some of the most egalitarian societies that lack formal structures of power (reviewed in Cheng et al. 2014), individuals assort hierarchically, with people occupying different strata within a group based on their standing in multiple culturally valued domains (Henrich and Gil-White 2001). The reason for the universality of both processes is that their presence provides a solution to the competition over relatively scarce social, sexual, and material resources that characterize most group-living species. These processes not only reduce costly conflict, aggression, and warfare, but may also generate and sustain cooperation within a group (Henrich et al. 2015). Although these relationships are present and important during adulthood, an understanding of the social world, and the positions that individuals occupy within that world, develops during childhood as early as in the first few months after birth.

Both the desire for peer relationships and status competition are present throughout the developmental periods of human life, although they take different forms and serve diverse purposes during each developmental stage. However, the means by which individuals both attain social status and successfully manage peer relationships seem to fall into two routes across a range of developmental periods: dominance and prestige (Cheng et al. 2010; Sijtsema et al. 2009; Hawley 2002). The vast and growing body of research supporting the dual model of social hierarchy during childhood suggests that prestige and dominance have distinct outcomes for different dimensions of status and that their efficacy is governed by the period of development and the group's social norms. The current entry surmises (1) the different types of status and peer relations in childhood and further outlines (2) the pathways to attaining status and managing peer relationships during childhood.

Social Hierarchy During Childhood

Children have an innate disposition towards social hierarchy. Evidence suggests that beginning in the

earliest years of life, even during preverbal periods, infants are remarkably skilled in recognizing and inferring relative social rank. For example, they make transitive rank inferences (e.g., if Ian is lower in rank than Jess and Jess is lower in rank than Harry, then Ian is lower in rank than Harry; Gazes et al. 2017) and show an expectation for these relationships to be stable over time (Mascaro and Csibra 2012). Moreover, infants as young as 10 months old use physical size to predict the results of conflicts of interest, specifically revealing an expectation for larger agents to win dominance contests (Thomsen et al. 2011). Given these exceptional abilities in forming rank-related mental representations, it is perhaps not surprising that preschoolers observe and react accordingly to the complex hierarchical dynamics of their group (e.g., subordinate peers defer to their dominant counterparts: Hawley 1999).

Although the valued resources that individuals compete over are often different to those during adulthood, status is of paramount importance during development, especially in adolescence (Cillessen and Rose 2005). High status children wield considerable power and influence and have access to valued social and material resources within their group (Hawley 1999). This power over resources continues into adolescence, with status being of principal importance for individuals and members of a peer system aspiring to befriend and imitate popular adolescents (Adler and Adler 1998). Moreover, these popular adolescents display greater emotional wellbeing, reporting fewer cases of anxiety and depression (Rodkin et al. 2000). During adulthood, an individual's relative standing within their hierarchy is equally important, as it impacts both social and reproductive success (McDougall and Vallancourt 2015; von Rueden et al. 2010). Status competitions are thus widespread across societies and social settings and highly prevalent across the lifespan.

Social Status

Although there is agreement on the importance of the individual rewards and group benefits of social status during childhood, there has been a divergence in theoretical conceptions of what it means

to be high in status. The current section outlines three measures of status. The first two measures are commonly used in Developmental Psychology: popularity, or social prominence, and social preference, also termed sociometric popularity (see Parkhurst and Hopmeyer 1998; Cillessen and Marks 2011 for a review). These two measures of status have a strong overlap during early childhood, but their association gradually decreases over time and they become distinct (Cillessen and Rose 2005). The third measure of status discussed, social rank, explicitly captures an individual's perceived social influence and agency. These distinct but overlapping conceptions of status are important, as they describe distinct dimensions of status during childhood, which have different antecedents and may produce divergent outcomes for both groups and individuals (reviewed in Mayeux et al. 2011).

Popularity

As a child, negotiating one's way through the hierarchies of the classroom, playground, and household can be difficult. Ethnographic accounts and evidence from classroom settings indicate that developmental hierarchies – especially those during adolescence – are competitive, with individuals struggling against one another to attain and defend their popularity and position within a group (Merten 1997). Popularity is defined as an individual's (or groups'/cliques') social centrality and eminence among their peers (Adler and Adler 1998). Popularity reflects an individual's reputation, signposting their impact, prominence, social influence, and power within a group (reviewed in Asher and McDonald 2009).

Popularity during child development is complex and is often governed by a combination of physical attributes, such as attractiveness and athletic ability (Dijkstra et al. 2009) and relational behaviors (e.g., assertiveness or kindness: Rodkin et al. 2000). In addition to these, the social structures of a group and social network processes have bearing on popularity during development. Evidence suggests that individuals assort and affiliate with those similar to themselves (sometimes called homophily), and this preference is also seen among children, who form friendships and

playgroups at higher rates with other children who share similar demographic traits (McPherson et al. 2001). However, two processes may govern similarity based on popularity over time: selection and influence. Selection refers to individuals preferentially choosing to associate with those similar to themselves on a given dimension (e.g., same-sex friendships), whereas influence denotes a subsequent gradual shift towards similarity between proximate individuals (some of whom may have been initially brought together through selection processes; reviewed in Steglich et al. 2010). Both selection and influence operate with regard to popularity during development (Dijkstra et al. 2013). Less popular individuals attempt to gain status by association with popular conspecifics (via influence processes), and popular individuals often try to maintain their status by preferentially selecting those similar in popularity as they risk their popularity decreasing via influence processes of being associated with those less popular.

Why do children and adolescents place such high emphasis on popularity? After all, popularity is not easily obtainable and being popular can be seen as a double-edged sword as it is also associated with a number of harmful outcomes, such as increased health risk-taking behavior and potentially poor academic outcomes (Mayeux et al. 2008). However, popular children attain a vast array of benefits. Highly popular children have greater access to a group's valued social, material, and informational resources (Reviewed in Hawley 1999). Popular children are believed to dictate the desirability of behavioral patterns within a classroom and are sought after as friends (Ellis and Zarbatany 2007). In contrast, being unpopular has a considerable, deleterious impact on children due to its relationship with victimization, which is associated with mental health disorders (Arseneault et al. 2006), poor academic functioning (Schwartz et al. 2005), reduced physical quality of life (Bogart et al. 2014), and in extreme cases even suicide (Bearman and Moody 2004). It seems that these “controversial” children, who are perceived as being popular, but relatively disliked, have great social power and influence among their peers (Coie et al. 1982).

Social Preference

In contrast to perceived popularity, status based on social preference – for example, as assessed using nominations of likability (Cillessen and Marks 2011) – has a weaker association with power and influence in children. Social preference represents a form of status that is founded on personal sentiment (Bukowski 2011). However, social preference (or sociometric status) is a somewhat controversial measure of status that is limited only to studies among children, as its relation to status outcomes is ambiguous and a finer distinction between likability, or warmth, and status has been drawn in studies during adulthood. It seems that it may be less complex, and less risky, to be socially preferred than to be popular, with the strongest antecedent of social preference being prosociality (Rodkin et al. 2000). Social preference seems to be rooted in relational intimacy, with prosocial and socially preferred individuals having closer friendships and a greater number of friendship nominations to those not socially preferred (Gest et al. 2001). These socially accepted individuals seem to be likeable and driven by communal goals, wishing to forge close relationships with their peers (Ojanen et al. 2005).

There are abounding benefits, and relatively few negative consequences, of childhood status derived from social preference. Socially preferred children do not come across as much adversity (e.g., bullying) as those who are not socially preferred, and social preference is not associated with risk-taking behavior (Buhs and Ladd 2001). Rather, being socially preferred is associated with cooperation among children, with likeable children holding the development of interpersonal skills as highly important (Rubin et al. 2007). Moreover, high social preference is associated with a strong sense of group belongingness and social support and has long-term benefits for a child's mental health and academic functioning (Ladd and Kochenderfer-Ladd 2016).

Social Rank

Akin to the concepts of popularity and social preference, a third conceptualization of status that has been studied within adult populations,

termed social rank, has been captured using peer-ratings (see Cheng et al. 2010; Cheng et al. 2013). This measure captures an individual's perceived social influence within a group and their perceived agency (Wiggins et al. 1988). Both social influence and agency reflect an individual's power, control, and status, which are central dimensions of an individual's social rank. To date, this measure has not commonly been used to measure status during childhood (the exception being an adapted version by Redhead 2016), and thus, little is known about how this form of status relates to important developmental outcomes, such as academic functioning, friendship, and health. Given the similarity of the construct to the dimension of popularity, such as increased social influence and power, and its distinction with likability (Cheng et al. 2013), similar developmental outcomes are expected. Additional research is needed to further understand how it operates during childhood.

The Routes to Social Status

Social asymmetries are multidimensional and relative status arises from two distinct systems of rank allocation: prestige and dominance (reviewed in Cheng et al. 2013). Although there are many factors that impact a child's status and behaviour, such as family dynamics and parental influences (Lukasewski 2015; Kapetanovic et al. 2017), the current focus is on the contributions of personality, behavioral disposition, and individual differences. A large body of research focuses on the unique relationships that specific determinants of social status, such as aggression and prosociality, have with popularity and social preference during childhood. However, the current entry emphasizes that these dimensions comprise two psychological profiles, prestige and dominance, that broadly predict an individual's status. It is important to note that the effects of prestige and dominance on social status and peer relationships discussed may be moderated by a group's norms, with dimensions relating to the two routes to status potentially having fluctuating efficacy based on the peer ecology (Laninga-Wijnen et al. 2017).

Dominance

Dominance is a rank acquisition system that is centered on the use of intimidation and coercion. Individuals strategically advertise their ability and propensity to inflict harm (either physical, material, or psychological), which urges others to yield to their will (Henrich and Gil-White 2001). Dominance is often associated with physical strength and size, as these are physiological cues to an individual's ability to triumph during agonistic conflicts or inflict harm (Archer 1988). As shown in Table 1, a dominance psychological profile is characterized by aggression, disagreeableness, narcissism, and manipulative tendencies, all of which aid in an individual's ability to propagate fear and coerce their peers (see Cheng et al. 2010). It is common for individuals high in dominance to have egocentric goals, aiming to increase their power and reach their social and material goals with little consideration about others (also referred to as "agentic goals": Sijtsema et al. 2009).

While aggression is an essential facet of dominance, children employ dual forms of aggression and these have divergent implications for their relative status with peers (reviewed in Dodge and Coie 1987). The first form of aggression, reactive aggression, is a response to anger, provocation, and frustration, which may have either positive or negative effects on status, depending on context, and is often associated with behavioral difficulties (Crick and Dodge 1996). Conversely, proactive aggression is a behavior that is a deliberate route for individuals to attain agentic goals and often has a positive effect on status during childhood (Pellegrini et al. 1999). The most pronounced form of proactive aggression during childhood is bullying, defined as repeated aggressive acts towards a peer, often lesser in size, status, or with fewer alliances (Olweus 1978). Bullying pervades cultures and species and can persist into adulthood (Volk et al. 2016). Those with more direct status-striving goals are most likely to be bullies and bullying does indeed increase an individual's popularity, even though bullies are as socially rejected by others in their group as their victims are (Sijtsema et al. 2009). It seems that if a

child were to perform aggressive acts with socio-political aptitude, just as the reminders of power often seen in dominance hierarchies among non-human primates, they accrue status, social influence, and positive attention (Hawley 1999).

The relationship that dominance has with status during childhood indicates those high in dominance are met with several benefits and costs. Aggressive adolescent males are perceived as highly attractive by the opposite sex and are high in status (Pellegrini and Long 2003). Among a group of children and young adults in Romanian state care, both males and females perceived as high in dominance were also perceived as high in social rank, were nominated more as friends, and had disproportionate control over the group's resources (Redhead 2016), of which has also been found in western classroom settings (Hawley 2002). However, the friendships that these individuals have tend to be low quality (Hawley et al. 2007). Children behaving aggressively receive greater visual attention from their peers, which is considered an indicator of social rank (La Freniere and Charlesworth 1983). Dominance-related behaviors seem most utilized and effective during periods of transition (e.g., between primary and middle or junior high school) and decrease across school years once hierarchies begin to stabilize (Pellegrini and Long 2002). Overall, as depicted in Fig. 1, current evidence suggests that dominance makes for popular and high-ranking, but disliked, children.

Prestige

Social learning is essential to human culture and individuals selectively learn from others based on a number of cues, of which are present during childhood (reviewed in Wood et al. 2013). Experiments assessing the microevolution of cultural traditions among children have repeatedly shown that the majority of children selectively learn from others, becoming followers to and imitating knowledgeable peers, while a minority may still produce innovations that create meaningful group differences (Whiten and Flynn 2010). Children may preferentially learn from peers similar to themselves on given attributes, peers high in

status, and to older individuals. Cues to a peer's competence and reliability also effectively govern children's learning. This discriminates social learning, biased towards deferring to and imitating those perceived as competent and knowledgeable, is termed prestige-biased social learning (Henrich and Gil-White 2001), and individuals possessing a prestigious psychological profile, or cuing prestige, are preferentially attended to by children (Chudek et al. 2012).

Prestige is a system of rank acquisition where individuals possessing skills in a culturally valued domain are provided freely conferred deference from peers through respect and admiration. Prestigious individuals not only have to cue an ability, but also a willingness to provide informational knowledge and help. Therefore, prestige is not solely dependent on competence, but also a moral, prosocial reputation (see Bai 2017; note that the current entry presents morality and

prosociality as traits that partially confer prestige). As shown in Table 1, individuals high in a prestige psychological profile are perceived as being agreeable, conscientious, agentic, and high in genuine self-esteem (see Cheng et al. 2010). Moreover, individuals high in prestige are characterized by behavioral tendencies that are antithetic to dominance and are perceived as highly cooperative, socially skilled, and capable advice-givers (Cheng et al. 2010). The social goals of individuals high in prestige are further distinct from those of dominants, with individuals possessing dimensions of prestige reporting an intrinsic motivation to pursue friendships with others (Hawley et al. 2007).

Given the association to social learning, and previous research consistently presenting a positive relationship of prosociality with status, prestige makes likable, socially accepted and, to some extent, popular children. The popularity of an

individual perceived high in prestige is potentially not as strong as with aggression (Ellis et al. 2012). However, these individuals are accepted by their peers and perform well academically (Padilla-Walker and Carlo 2014). Among a group of children and young adults in Romanian state care, individuals perceived by their peers as being highly prestigious were high in social rank, more central in networks of cooperation (i.e., toy and resource sharing), and received high numbers of friendship nominations (Redhead 2016). Those perceived as high in prestige-related facets are often advice-givers (Hawley 2002) and enjoy the resource-related benefits of long-term friendships (Pellegrini et al. 1999). Furthermore, research suggests that individuals high in prestige-related facets have greater social support, receiving greater numbers of reciprocated friendships, of which are high in intimacy and low in conflict (Hawley et al. 2007). These prestige-related behaviors exhibit an increase between childhood and adolescence and are somewhat stable

strategies throughout adolescence (Eisenberg et al. 2009). As with adults, evidence suggests that the behaviors associated with prestige increase a childhood group’s ability to cooperatively and collaboratively learn (Padilla-Walker and Carlo 2014). Overall, as shown in Fig. 1, prestige provides distinct hierarchical benefits to dominance for both groups and individuals during childhood, bolstering a child’s social acceptance but not necessarily their popularity.

Although research directly assessing the effects of prestige and dominance on social status has illustrated that the two profiles are either uncorrelated (Cheng et al. 2010; Cheng et al. 2013) or negatively related (Redhead 2016), work within developmental psychology indicates that there may be bi-strategic approaches (i.e., the deployment of both prestige and dominance simultaneously) to status acquisition. A number of studies have suggested that these bi-strategists may have found the optimal route to “getting ahead and getting along” (Hawley 1999). A specific

Status Competition and Peer Relationships in Childhood, Fig. 1 Relationships between prestige, dominance, and dimensions of social status during childhood. Arrows

indicate the theoretical directionality of the effect and plus/minus symbols illustrate whether the effect is positive or negative

form of social competence characterizes these bi-strategists. They understand social rules and have a similar profile to prestige. However, they also utilize aggressive, forceful acts and view relationships as avenues to resource acquisition (Hawley et al. 2007). As shown in Fig. 1, through the positive association with both popularity and social acceptance, bi-strategists enjoy intimate relationships (Hawley et al. 2007) and maintain high status reputations (Cillessen and Rose 2005).

Conclusion

There are two routes to attaining social status and managing peer relationship during childhood: prestige and dominance. As shown in Fig. 1, prestige-related behaviors and traits are strongly associated with social acceptance and social rank, while evidence indicates that those related to dominance are associated with a child's perceived popularity and social rank. These different associations with status allot distinct benefits and costs related to prestige and dominance during childhood. While there is an expansive body of research assessing the impact of certain dimensions of prestige and dominance during childhood, there is limited empirical evidence directly testing the dual model of social hierarchy in a developmental context, of which provides a fruitful platform for future research.

[Dominance](#); [Hierarchies](#); [Status](#)

Definition

Social hierarchies are emergent social structures demarcating the relative power, status, and dominance of individuals and groups with respect to their ability to access fitness-enhancing resources.

Introduction

Social hierarchies are a fundamental part of social life among humans and many other social species. Dominance orders reflect differences in superiority of access to fitness-enhancing resources, including food, territory, and mates. Evidence for elementary dominance orders exist for dragonflies, pecking orders exist for chickens, and complex and often fluid dominance orders exist for primates, including humans. Human hierarchies may be more complex than those in other species, but all hierarchies ultimately reflect individual differences in the ability to gain and maintain access to fitness-enhancing resources. The intensity of competition for resources varies across species and explains species-typical differences in social hierarchies. Chimps, for example, have tyrannical male-led hierarchies in which alpha males command disproportionate access to resources and mates. Once sexual maturity is reached, male chimps tyrannize female conspecifics before attempting to establish dominance over other males. This process involves aggressive posturing and physical violence. Bonobos, on the other hand, have evolved matriarchal hierarchies that produce much less dominance competition, particularly between males and females. Ritualized sex – both homo- and homosexual – is used to regulate bonobo hierarchies.

Hierarchies suffuse human social relations. A key part of social life is finding access to mates, and for this reason, human hierarchies reflect processes of sexual selection. Humans have many tactics for negotiating their positions in hierarchies, including gossip, direct and indirect forms of aggression, displays of creativity, as well as more cooperative tactics, such as forming

coalitions with those with shared interests. Hierarchies are mediated by hormones, which both reflect and reinforce individual positions in hierarchies. Finally, individuals who are lower in social hierarchies are likely to suffer from health problems and die younger than those at the top of hierarchies. Given that hierarchies are critical to human life, it is not surprising that aggression is strongly connected with competition over positions in hierarchies. In what follows, these and other key facets of hierarchies for human social life are explored.

Evolution and Social Hierarchies

Male Armaments and Female Choice

Secondary sex characteristics such as muscular bodies and low-pitched voices were designed for effective male intrasexual competition, to intimidate or defeat rivals and obtain high-quality mates. However, these armaments may also be particularly desirable to females insofar as they are honest signals of health and virility. The immunocompetence handicap hypothesis maintains that male armaments such as muscularity are honest signals of health, a well-functioning immune system, and superior genetic quality. The signal is kept honest (i.e., reliable) because the reproductive hormones used to make and maintain them (i.e., testosterone) suppress immune function and increase disease rates. As such, high- but not low-quality males can risk high levels of testosterone and advertise this through exaggerated secondary sexual characteristics.

Short-term strategizing females are particularly attuned to these signals of mate quality – they generally prefer dominant males who possess traits that confer high-quality genes to their offspring. Strong, muscular men generally have more sexual partners and start having sex earlier in life, and short-term strategizing females prefer muscular, socially dominant men. Muscle mass is moderately heritable, suggesting that short-term strategizing females may find these traits attractive because they will be passed on to offspring, increasing inclusive fitness. More generally,

females prefer dominant male behaviors (i.e., social presence, direct intrasexual competitiveness) and find males with dominant facial features, bodily features, and vocal masculinity sexually attractive, especially when fertile. Male faces rated by women as more dominant, attractive, and masculine also tend to have greater strength, suggesting that those with attractive, masculine facial features (e.g., pronounced jaws, cheekbones, and brow ridges) may occupy the top tiers of hierarchies due to their physical dominance and formidability. Indeed, a study of military cadets found that those with more masculine, dominant faces were likely to occupy a higher rank within the military academy in West Point during junior and senior years (Mazur et al. 1984).

Ultimately, short-term strategizing females may have developed a preference for dominant behaviors and armaments like muscularity to maximize their chances of mating with socially dominant, high-status males to confer material and genetic resources to their offspring in the short term. However, females generally do not prefer dominance and aggressiveness in long-term mates. Individuals perceived to be highly aggressive and domineering are also rated as more promiscuous and less desirable as spouses. Indeed, short-term strategizing men who allocate more resources to mating versus parenting are higher in testosterone (Archer 2006), suggesting that masculine men with elaborate armaments may be promiscuous and therefore undesirable long-term mates. Masculine, physically attractive men are more successful at mate poaching and have more extra-pair copulations (Gangestad and Thornhill 1997), rendering them particularly suitable for short-term rather than long-term mating. Further, while effect sizes are small, it has been shown that men with high testosterone levels tend to occupy lower status (e.g., blue collar rather than white collar) occupations due to greater antisocial behavior, lower intelligence, and fewer years of schooling, further suggesting somewhat limited parental investment abilities. Thus, while male intrasexual competition led to the development of male secondary sexual characteristics to defeat rivals, a strong female preference for these characteristics among short-term (but not long-term)

strategists likely aided in their propagation and elaboration.

Status Cues and Female Choice

Status competition is intertwined with male intrasexual competition, as females – particularly long-term strategists – value cues to resource acquisition abilities and status, including males' achievements and ambition, older age, character, socioeconomic status, and even height, which is a cue to physical health and social dominance. Given the importance of male status striving and resource acquisition to females, insults directed at males' poor financial prospects are particularly effective in undercutting male rivals in intrasexual mate competition. In Buss and Dedden (1990), undergraduates rated the following status-related insults among the most effective in making a rival male appear undesirable to a female: the rival's financial resources (saying "he is poor"), his strength ("I can defeat him physically"), his ambition ("he has no goals"), and his social connectedness ("he is unpopular"). Unsurprisingly, men experience jealousy when facing wealthy, high-status males, and females are more envious of fellow females with wealthy, resource-rich husbands who can provide for them and their offspring in the long term.

Female Intrasexual Competition and Status

Comparative evidence suggests that female intrasexual competition contributes to dominance behaviors and status striving among women. Among female primates, those with higher-status positions often have superior mating opportunities and can suppress the fertility of subordinates. However, some have argued that status striving is not as important for human females as for males in a mate competition context. Human females at the top of the hierarchy do not necessarily receive the substantial reproductive benefits from social status that males do, as dominant females are generally not rated as more attractive or desirable to potential male mates. Ultimately, status striving – particularly through aggressive means – is likely more strongly implicated in mate competition processes for human males than for females.

Attaining and Maintaining Social Status

Aggressive Tactics

Direct and indirect forms of aggression can be used to maintain or enhance social position. Direct aggression includes physical fighting (e.g., punching, kicking), as well as verbally assaulting individuals with whom one is competing (e.g., using personal insults or racial slurs). Among honor cultures, such as those in the American south, people are more likely to use direct aggression and violence to protect their threatened social standing (i.e., when insulted) and to maintain a sense of justice (Nisbett and Cohen 1996). Relative to females, males are more likely to use aggression and displays of athleticism as status-striving tactics, whereas females tend to solicit aid from others and enhance their appearance to move up the social ladder (Kyl-Heku and Buss 1996), which aligns with extant research and theorizing on sex differences in aggression and mate competition tactics.

Indirect aggression consists of covert social manipulation and includes tactics such as rumor spreading, malicious gossip, and social exclusion. Ultimately, aggression is a strategy to enhance the aggressor's status, reputation, and hence their survival and reproductive prospects. Indeed, perpetrators of indirect aggression are generally seen as popular, high status, and central in their social networks.

Cooperative Tactics

Beyond aggression, there exist a variety of pro-social status-striving tactics that are more cooperative and less antagonistic in nature. Kyl-Heku and Buss (1996) found several commonly reported tactics for negotiating status hierarchies, among them industriousness/knowledge, social display/networking, aid accrual, and autonomy. The use of certain tactics, such as industriousness (e.g., working hard), significantly predicted increased academic degrees, promotions, and higher salary, suggesting that they can be effective in attaining high status. Additional self-presentation-based strategies identified in the

literature include obtaining and displaying resources and demonstrations of sacrifice and loyalty to the in-group.

Within groups, higher status can be attained when one makes substantial contributions to the group and its performance, as when devoting time and effort to group goals and providing expertise. This type of status striving is driven by prestige – possessing and sharing culturally relevant knowledge and skills – rather than by physical dominance. Coalition formation with fellow in-group members or with other groups can also help individuals and groups maintain and improve their relative positions within a hierarchy. Indeed, Simpson and Macy (2001) found that when low-power individuals were given the opportunity to form a coalition with one another, their bargaining status, and total earnings in an economic game increased.

Communication Tactics

Mazur (1985) suggests that verbal and nonverbal conversational style signals social status. For instance, dominant, higher testosterone individuals generally use more direct eye contact when speaking, more frequently interrupt lower-status individuals, speak loudly or angrily, set the mood and pace of the conversation, introduce and terminate topics of conversation, and have more expansive nonverbal postures (e.g., hands on hips, legs spread apart). Nonverbal cues such as facial expressiveness and successful interruptions have also been found to associate positively with social standing. Using these strategies could help an individual maintain their high social standing or attain a higher position, provided they can legitimately occupy that position. Stress management abilities while speaking with others may also help solidify individuals' positions within a hierarchy. High-status individuals have a lesser stress reaction (e.g., lower pulse rate) during speaking than lower-status individuals, suggesting they may be more comfortable asserting themselves in social scenarios and can more effectively manage social stressors than their subordinates (Mazur et al. 2015).

Hierarchies and Hormones

Research has focused on the role of testosterone (T) in mediating aggression and physical dominance, particularly among men. Individuals use aggression as a forceful means of attaining or maintaining status or of defending a threatened position within a hierarchy. Indeed, Griskevicius et al. (2009) found that status motives contribute to increased aggression among both males and females, although males tend to use direct forms of aggression (e.g., hitting, yelling), whereas females prefer more indirect forms of aggression (e.g., malicious gossip, social exclusion). Across many species including humans, modest associations between testosterone levels and aggression have been reported. However, the testosterone-aggression link is debated, and some argue that testosterone is more directly connected with dominance signaling than with aggression per se (see Mazur et al. 2015). Regardless, links between testosterone and the development of male armaments suggest that hormones are strongly implicated in intrasexual competition and status-striving behaviors, aggressive or otherwise.

Testosterone and Armaments

Testosterone causes the development of secondary sexual characteristics, including increases in muscle mass, more robust brow ridges, high cheekbones, facial and body hair, and a lower fundamental vocal frequency. These physical traits play a role in signaling dominance and aid in successful fighting. In humans, greater strength is associated with higher testosterone in men, and muscle mass is associated with men's higher testosterone levels (Bhasin 2003). Additionally, males with lower-pitched voices (a trait associated with higher T) are perceived as more physically dominant than those with higher-pitched voices. Thus, testosterone contributes to the development of male secondary sex characteristics, and these characteristics contribute to perceptions of male dominance and status.

Testosterone and Dominance

Comparative evidence supports the testosterone-dominance link. For instance, testosterone removal

(through castration) has been shown to decrease aggressiveness and social dominance in rats. In a study of rhesus monkeys undergoing group reformation, the new alpha male experienced testosterone increases, while the previous alpha male, newly subordinate, experienced an 80% drop in testosterone levels (Rose et al. 1975). In a study of human teenage males, testosterone levels were positively associated with leadership capacities among those with nondeviant (rather than deviant) peers, suggesting that there is an interaction between T, social groups, and dominance (Rowe et al. 2004). In their examination of data from US Army veterans, Mazur and Booth (2014) found that testosterone is linked to aggressive and dominant behavior, including juvenile delinquency, violence, and vagrancy, as well as alcohol and drug use.

Testosterone and Competition

While higher testosterone can contribute to higher social standing within a hierarchy, higher social status can also contribute to testosterone increases, creating a status-testosterone feedback loop that may keep dominant, high testosterone individuals at the top of the hierarchy and lower testosterone individuals at the bottom. Among nonhuman primates and among university wrestlers, male tennis players, and chess players, victors in competition experience greater increases in testosterone levels than those who are defeated in competition, who sometimes experience decreases in testosterone. Even merely visualizing a future victory in a dominance contest or anticipating future competition can increase human males' testosterone levels in certain situations. The comparatively higher testosterone levels of victors could help them win future contests using aggression and dominance behaviors, thereby aiding in effective status maintenance and status striving. In line with this reasoning, Carré et al. (2013) found that male victors experienced increases in T, and this T reactivity after competition was a mediator between winning and later aggressive behavior among males.

Female Hormones

Among females, hormones including estradiol and testosterone have been linked to status striving. For human females, estradiol may serve a function analogous to testosterone, as it is linked to dominance in women and has been shown to increase following victory in a contest for those with high-power motivation (Stanton and Schultheiss 2007). Further, women with higher estradiol levels tend to have higher implicit power motivation.

Testosterone may also be associated with dominance and high status in females, particularly among those high in basal cortisol. Examining female college athletes, Edwards and Castro (2013) found that those competing had higher T levels than those on the sidelines. Further, higher testosterone before a game was associated with occupying a higher-status position on the team, but only among females who had relatively low cortisol levels prior to the game. Zilioli et al. (2014) found that when the outcome of a competition between females is uncertain, competitors experience a T boost, perhaps due to the possibility of future victory. Finally, females with congenital adrenal hyperplasia (CAH), a condition involving abnormally high prenatal androgen exposure, have been found to engage in higher levels of direct aggression relative to non-CAH females (Pasterski et al. 2007). Overall, the links between hormones and dominance behaviors in competitive contexts suggest that hormones shape hierarchy structure, and hierarchy structure shapes hormone levels among both males and females.

Hierarchies and Health

High status confers many potential fitness benefits to humans and nonhuman primates, including longer life and better health, more mating opportunities, and material resources (Ellis 1995). These detrimental effects of lower status exist along a continuum, with those in lower socioeconomic status (SES) positions experiencing more negative outcomes than those on top. Indeed, lower status is associated with physical and mental health problems. In stable hierarchies with

extreme inequality, adverse health outcomes such as physical and psychological stress are particularly likely for those at the bottom, who receive the least social support and resources (reviewed by Abbott et al. 2003). While individual differences exist, occupying the lowest rungs of the social ladder can contribute to chronic stress, particularly in steep and stable hierarchies. Chronic stress, in turn, is associated with immune suppression, hypertension, high cholesterol levels, testicular atrophy, increased risk of miscarriage, and increased risk of developing heart disease (Brunner et al. 2002), diabetes, and stroke. Among humans, lower SES contributes to higher infant mortality, decreased likelihood of using many types of health care (e.g., vaccinations and dentist visits), and higher heart disease and stroke mortality (CDC 2009).

These SES-based health disparities persist among employed individuals with health-care access, indicating they do not arise from differential access to health care. Those on the lower rungs of the social ladder are more likely to smoke, drink excessively, have sedentary lifestyles, poor diets, and fewer preventative health opportunities such as health club memberships and safe parks. However, these lifestyle factors account for only a third of the SES gradient in health outcomes (Sapolsky 2004).

Employment Rank

Working a low-status job is associated with a host of adverse health outcomes. For instance, having a low-status career is associated with low heart rate variability (HRV), which is a predictor of heart disease (Hemingway et al. 2005). Lower HRVs have also been found among individuals with small social networks, depression, and low job control (e.g., an unstable position within the hierarchy) relative to those with more social support and job control. In the classic Whitehall studies, employment rank was positively associated with disease mortality – including heart disease mortality – among British civil servants (Marmot et al. 1978). These detrimental effects of low-status positions may stem from a high ratio of costs relative to benefits in the workplace. Indeed, a high cost-reward ratio at work is associated with

an increase in coronary heart disease, poor mental health, and poor physical health.

Comparative Evidence

Nonhuman primates at the bottom of social hierarchies do not always experience the chronic stress responses that humans do. Among some primates, those at the bottom of hierarchies actually exhibit lower cortisol levels than those at the top. Some reasons for this are that primate social structures are diverse – not all consist of highly unequal hierarchies with stable boundaries, and primates engage in reconciliation and peacemaking behaviors that may support those in the lower rungs of the social ladder (see Abbott et al. 2003).

Despite this, in some species, subordinate primates experience worse health outcomes than those at the top of the hierarchy. For instance, in some primate groups, those occupying the lower rungs have higher cortisol, particularly when they are experiencing more stressors and a lack of social support (Abbott et al. 2003). Among female primates, high status is associated with getting pregnant more quickly, higher offspring survival rates, and less aggression from fellow females (Hrdy 1981). In turn, among low-status female primates, ovulation can be suppressed by stress brought on by aggressive, high-status females. High-status females can also contribute to lengthening of the menstrual cycle, maturational delay, and spontaneous abortion in subordinate females (Hrdy 1981). Among both humans and nonhuman primates, high-status females are likely to mate with high-status males, thereby conferring the good genes and superior health to her offspring.

Conclusion

Hierarchies emerge from competition over fitness-relevant resources. Given that such competition is integral to reproductive fitness, it should be no surprise that hierarchical social structures are found across social species. It appears that humans and other animals have adaptations to negotiate hierarchies – to maintain position and to strive for higher-status positions, for instance. Occupying a dominant, high-status

position confers numerous survival and reproductive benefits, including access to high-quality mates. Hierarchies are formed partially on the basis of hormonal biochemistry interacting with the social environment. One's social position can, in turn, shape physiology and subsequent dominance behavior. Social hierarchies have a profound influence on health, affecting mortality and morbidity for a variety of diseases, and shape psychological well-being. Given the plethora of benefits that high status confers, individuals strive to maintain their high status and improve their social rank using a variety of context-dependent strategies, including both aggressive and cooperative tactics.

Definition

Stepfamily is defined as “a unit that is created when two adults form a household in which one or both brings a child from a previous relationship” (DiVerniero 2011, p. 3).

Introduction

There are many different types of stepfamilies. According to Papernow (2018), “Stepfamilies come in many forms. Stepouples may be married, or unmarried” (p. 3). For example, a family that is shaped by two individuals and only one of them has children is called a “simple” stepfamily. A different type of stepfamily includes an adult who is either married to or cohabitating with another adult, and both adults have children; these are called “complex” families. A stepfamily is created once a parent takes a new partner, by living together, or due to divorce. Previous paternal relationships may have ended in divorce, death, or breakup in the case of unmarried couples. The divorce average has fallen in the United States, with the exception of those more than 50 years of age, with the rate doubling between 1990 and 2010 (Brown and Lin 2012).

Thus, the increasing numbers of new couples are over the age of 50, some with adult children and even grandchildren. All these stepfamilies face five challenges for intimate relationships (Papernow 2013). This entry will describe the stepfamily, explore the challenges that face stepfamilies, and examine the myths and realities regarding stepfamilies.

Challenges Faced in the Stepfamily

The first challenge faced by stepfamilies is that insider/outsider positions are intense and stubborn. The strong fetters of the family, common history, and common values in the structure of parents and children create the bonds for strong parent-child relationships. However, the parents can become torn between the needs of their children and their partners. Culture also plays a role in the formation of this challenge. The Anglo-European family standards draw firm boundaries around the nuclear family, setting a context for competition. By contrast, African American traditions in “childcare” and “informal adoption” support cross-family cooperation (Gonzalez et al. 2014). These differences may explain the discovery that adolescent black-stepchildren in many large samples of married stepfamilies show more resilience than their white counterparts (Adler-Baeder et al. 2010).

Cultural standards can also restrict, or support, the participation of nonresident fathers. In Japanese and Latin stepfamilies, nonresident parents are often excluded, even from the family conversation (Papernow 2013). In the United States, nonresident Latino parents have significantly lower levels of post-divorce involvement than Anglo-American or African American parents (Stykes 2012). In sharp contrast, non-African American parents, both married and single, keep participation higher than Anglo-Latin parents through a variety of measures (Papernow 2013). The lack of data available across cultures suggests the existence of marginalized stepparents in cultures where the “nuclear family ideology” is very strong. Second wives in Hong Kong, for example, are referred to as “worn shoes” (Papernow 2015).

Therefore, there are many factors that impact the insider/outsider positions within stepfamily relationships.

The second challenge faced involves children struggling with losses, loyalty binds, and changes. According to a study conducted by the American Academy of Child and Adolescent Psychiatry (AACAP) (2015), it takes one to 2 years for amalgamated families to regulate and adjust to the changes. However, couples who are practical in reducing and tackling potential matters will create adjustment efficiently. Sibling rivalry is an example of a big challenge in a stepfamily. Children do not like to share parents. In fact, while a new relationship is a wonderful gift for adults, children – even adult children – often experience their stepfamily as yet another set of losses (Cartwright 2008). This problem can be solved if the husband and wife talk peacefully to resolve the issue and never blame each other. Everyone desires attention in a stepfamily. When the number of children increases in the family, the children feel that they are not obtaining the attention they are accustomed to getting. Additionally, amalgamated families generally have less time and cash for every child’s extracurricular activities or for family outings due to the increase in the size of the family. This problem can be sorted out by giving each child some positive time.

The third challenge involves dividing parenting tasks between parents and stepparents. “Stepfamilies by their very nature are complex and infinitely varied” (Papernow 2013, p. 3). Therefore, stepparent discipline often becomes a challenge. However, previous research has convincingly demonstrated that biological parents must retain control of discipline issues so that children and their parents can have a satisfactory relationship (Pylyser et al. 2018). Whereas once the biological parents’ partner was somebody to have fun with, they become an authority figure, which may cause some issues within the home. However, an amalgamated family remains simply a family despite the existence of such issues. Although there can be growing pains, squabbles and some moments of discord, everybody can eventually go on with the new state of affairs (Morin 2019). As the nature and complexity on

the part of stepfamily relationship have effects on stepparent discipline, the parenting tasks in the family need to be maintained to overcome relationship mismatches.

A fourth challenge can be connected to a new family culture which must be formulated in the presence of already established cultures. This is a challenge which step families experience when the two parents come from different ethnic and sociological backgrounds. It is represented in the family members' common understanding about noise, chaos, holiday rights, money, etc., and it exists in parent-child relationships rather than the relationships between spouses. The differences, large and small, saturate daily life. Successful families slowly adopt a new family culture while respecting and honoring the traditions, values, and family customs in place.

The fifth challenge involves Ex-spouses (other parents) who are part of the family. Children have another parent, alive or dead, who was nurtured or abused, outside the nuclear family. Children's well-being is the highest with positive parental behavior, joint cooperation with parenting, and when children feel safe with all adults in their lives (Papernow 2013). This challenge is considered as having the least impact on the new family, as it is often avoided by explaining that there were no other choices than starting a new family. Also, children seem to grow out of making complaints about their loss of an ex-member of a family once they understand the new situation. Finally, despite all the challenges that seem to occur along with the formations of stepfamilies, still there are many new families are formed every day and still parents believe this type of family is a better solution to the traditional family breakdowns and relationship failures.

Many children that stay with their foster parents have faced injustices. Typically, stepparents have abused children that are not of their own genetic makeup. When children stay in a household without any genetic parent, the stepparents tend to mishandle them and instead, focus on their own genetic tree that they expect to extend to further generations. Abuse of stepchildren is rampant as compared to that of children living with their genetic parents. They foster parents tend to

include violence and aggression in modeling stepchildren, especially those that are not their blood relatives (Skånland 2012). However, even genetic fathers kill their own children and subject some of them to social injustices including sexual violence. For example, genetic fathers killed 178 children aged below 5 years between 1974 and 1990 based on a study conducted by Daly and Wilson (1983). About 67 stepchildren were killed by their foster parent although the risk of being killed by a stepfather is still higher than that of being killed by genetic parents. Additionally, children living with single parents, either genetic or stepparent, are at higher risks of physical, sexual, and emotional abuse as compared to when those parents are living with their biological offspring. Consequently, research proves that stepchildren are often injured as compared to biological children since the abuse rates among the latter group have declined in recent years. Also, children living with disadvantaged families, specifically those experiencing abject poverty, experience abuse as compared to those in socio-economically advantaged homes (Skånland 2012). This implies that children living with stepparents are at higher risks of abuse and poverty is a major contributor to the increased risk. Other than poverty, age is equally a perpetrator of child abuse since evidence proves that younger parents abuse both genetic and nongenetic children as compared to the aged.

Myths and Reality about Stepfamily

In modern America, one in three people are a part of a stepfamily. There are a lot of misconceptions and myths about stepfamilies. Professionals have not paid much attention to the requirements and problems faced by these families. The most common myth in society is the Wicked Stepmother. Whether it is fairy tales of centuries past or modern cinematic plots, this stereotype continues to dominate society's thinking about mothers (Christian 2005).

There is also the myth that a partner in a stepfamily works to fit in someone else's role in order to recreate the first family, which is not true

(Jacobson 1979). The reality is that stepparents build their family in keeping with their own values and background. The thought that stepparents are always bad and evil is far from reality. The truth is that stepparents need a cheerful, healthy family like anyone else. Stepparents are not universally evil people. This does not, of course, mean that every parent is great or that they never do any wrong. The perception that partners decide to form a stepfamily for their own gains is false and ignores the tremendous modification and sacrifices they are doing to settle in with their new family. TV shows, fiction, and films portray ex-parents as adversaries, always in disagreement (Jacobson 1979). The fact is that a stepfamily is a way to lead a peaceful and respectful life in many cases where marriages are not successful and lack compatibility. It is in the interest of both children and adults to be in a civilized stepfamily rather than to drag on in the unhappy relationship, everyday confrontations, violence, and unpleasant situations.

Another myth is that co-parenting is the sole method for families. The truth is within the high-conflict situation in the family, parallel parenting will be the foremost effective selection for families (Jacobson 1979). It is often said that the kids in stepfamilies cannot love all of their parents-biological and stepparents. In reality, if children are treated well, inspired, and educated to have compassion for all, they will overtly love all adults in their family. Children who are not treated well in stepfamilies can feel extreme anxiety and stress concerning their family dynamic. However, children who are motivated to have positive, loving relationships with all live happily in the stepfamily (Jacobson 1979).

Conclusion

In spite of the arguments that are warning about growing lack in success of second and later marriages, there are several stepfamilies who have reached some extent where members of the family can actually say they have achieved happiness. Wilson (2014) argues that the cultural expectations surrounding mothers and wives began to

improve in the early nineteenth century. Following developments in children's literature and educational literature, Wilson claims that the growing cultural importance of domestic life, as well as the belief in the potential for personal reform promoted by the Second Great Awakening, led to a revision of the qualities and roles of the stepmother.

The importance of school-family-community (SFC) partnerships have long been established; but, a lot of analysis, practices, and policies are required to perceive and support numerous socio-cultural contexts of children coming from stepfamilies who experience an educational set back due to the changed environment. Families may openly discuss the problems and stresses that they observe in the newly created stepfamily. With the use of Epstein's model on SFC partnerships, strains faced by children and stepfamilies can be addressed by the following: parenting, communication, volunteering, earning at home, and cooperation with the community (Epstein, Sanders, Sheldon, Simon, Salinas, Jansorn, Hutchins, 218). Cultural disparities, educational problems, and other constraints should be openly shared by all stakeholders. Respect towards each other, trust and appreciation of observations made by parents and school authorities should be ensured. When a strong partnership is developed students' educational and nonacademic outcomes are improved (Paik et al. 2019). The increasing numbers of new step families contain couples of different ages in addition they include children of school ages and some with adult children. All these stepfamilies need to be integrated in community programs in order to avoid the children being trapped in evolving intimate relationships as a result of the new form of familial structures. This entry provided a description of this new social symptom known as the stepfamily, and it examined the challenges, presenting some of the myths and misconceptions about such a sociological phenomenon.

Step-Parenting

Sebastian Schnettler¹ and Kai Willführ²

¹Department of Social Sciences, Carl von Ossietzky University of Oldenburg, Oldenburg, Germany

²Carl von Ossietzky University of Oldenburg, Oldenburg, Germany

Definition

(Co)parenting of a partner’s child which is not one’s biological child.

Introduction

Step-parenting takes on many different forms and may have different causes. Historically and across societies, there is variation in what constitutes the most common causes for stepfamily formation: Whereas in modern industrial societies increasing rates of separation and divorce along with re-partnering and multiple-partner fertility have been major drivers for the formation of stepfamilies (Steinbach 2010), historically stepfamilies were mostly formed after the death of one biological parent, often out of economic necessity (Hill and Kopp 2013, p. 33).

In both cases, what constitutes a stepfamily – from the perspective of a child – is that children share the household with one biological parent and his or her current partner who is not a biological parent. Possibly, and this is more characteristic for modern stepfamilies, the child has a second parental home where the other biological parent

lives with or without a new partner who would constitute a second stepparent. If one or both biological parents have additional children with their new partners and/or the stepparents have children from (a) previous relationship(s), half- and/or stepsiblings may be present in one or both households (Schnettler and Steinbach 2011). Stepfamilies can thus be characterized by various degrees of family and household complexity (Thomson 2014). Recent research on stepfamilies reflects on the importance of these multiple-household family structures with regard to potential outcomes for children (e.g., Brown et al. 2015; Schnettler and Steinbach 2011), especially at a time when joint parental custody is on the rise with, in some cases, an equal share of time spent in either of the two parental homes (Steinbach 2019) (Fig. 1).

The presence of a stepparent does not necessarily contribute to the well-being of the child to the same degree as the presence of two biological parents. Research shows overwhelming evidence for the existence of a so-called stepgap (Delongis and Preece 2002), that is, a mean difference in

outcomes between children living with and without stepparents on a range of indicators, in both contemporary as well as historical societies. This includes a range of subjective outcome indicators like children's assessment of their relationship with their parents and a range of objective measures like parental investment of time and money, children's academic achievement, psychological adjustment, child abuse and mistreatment, behavioral problems, and even cortisol levels as indicator of social stress (Anderson et al. 1999a, b; Brown and Rinelli 2010; Coleman et al. 2000; Daly and Wilson 1985; Flinn and England 1995; Hamilton et al. 2007). The direction of the stepgap is usually such that, on average, children living in a stepfamily have worse outcomes than children living with two-biological-parent families. Although part of the stepgap may be attributed to between-family differences (e.g., Buller 2005), Schnettler and Steinbach (2011) show that a stepgap persists after taking differences between families into account. In their study, the stepgap in subjective assessments of the child-parent

Step-Parenting, Fig. 1 Schematic illustration of a stepfamily from the perspective of a child (ego). Genetic relatedness is indicated by colors. The relationship of the absent biological parent to his or her children (ego and full siblings) might be of similar importance as the relationships between the absent biological parent with the present biological parent and with the present stepparent (indicated by

dashed lines). Likewise, the sibling composition in either household is of importance. The stepparent's behavior toward ego might be different if the stepparent has biological children with ego's present biological parent (half-siblings to ego) or if children of the stepparent from a former relationship (stepsiblings) are present in one of the two households of the two biological parents, too

relationship even roughly follows a gradient along the lines of genetic similarity in sibling dyads, based on pairs of monozygotic and dizygotic twins, full-, half-, and stepsiblings from the US Adolescent Health Study.

Nevertheless, the persistence of a stepgap in studies using a within-family research design is no proof that the difference is biologically hardwired (Schnettler and Steinbach 2011). Theories in evolutionary biology provide reasoning for why parents would be biased in their investment toward biological versus stepchildren. One central such reason would be (the lack of) genetic relatedness that – according to kin selection theory – should play a decisive role in steering parental investment patterns and other forms of altruistic behavior. Yet, there are also conditions under which, even from an evolutionary perspective, parents may strategically provide investment to their stepchildren. Furthermore, as evolutionary psychology has amply demonstrated regarding other adaptive problems in human behavior, psychological mechanisms that have evolved in an ancestral environment may prove maladaptive in the modern environment (Barkow et al. 1992). There may exist social contextual conditions in which we would expect smaller or nonexistent differences in stepparent- versus biological parent-child ties, even though evolutionary biology predicts that preferential treatment of biological kin is adaptive. Genetic relatedness is but the ultimate evolutionary explanation, relating to underlying mechanisms. More direct, proximate mechanisms may involve co-residence duration, similarity in looks (phenotypical similarity), or similarity in smell (olfactory cues) that all affect how children are treated and which can result in different treatment of biological vis-à-vis stepchildren. In this interplay of multiple potential mechanisms lies the possibility that the size of the stepgap is malleable by contextual differences, such as differences across time and space in the likelihood that stepparents and stepchildren live together in one household. Such differences provide potential leverage for policy-making that aims at improving parent-child relationships in stepfamilies.

Previous research has investigated different potential mechanisms for this stepgap: The

majority of studies with a background in the social sciences as well as in psychology has focused on stressors associated with parental separation or death and with life in (complex) post-separation families, and on stepfamily selectivity. Evolutionary research, on the other hand, has emphasized the evolved motivational and behavioral patterns which may play an important role in producing the stepgap.

Step-Parenting in the (Standard) Social Sciences

Family research offers two major hypotheses on potential causes of the stepgap: the selection hypothesis and the stress-mediation hypothesis (Coleman et al. 2000; Hadfield et al. 2018). According to the selection hypothesis, “multiple transitions and negative child outcomes may be associated with each other through common causal factors reflected in the parents’ antecedent behaviors and attributes” (Fomby and Cherlin 2007, p. 181; cited in Hadfield et al. 2018). Multiple transitions are (repeated) parental separation and re-partnering events that produce more or less complex types of stepfamilies. In this view, it is unobserved heterogeneity between different family types which is also responsible for the stepgap in developmental outcomes. Better data availability in the form of repeated measures over time and for siblings in the same families has made it possible to test this hypothesis empirically. One study using longitudinal data, for instance, shows that parental attention after the birth of a new biological child shifts from older children to the newborn roughly to the same degree in two-biological-parent families and stepfamilies (Stewart 2005). This seems to imply that the stepgap may partially be driven by a birth-order or age effect. Yet, in a within-family comparison of siblings living in the same families in the USA, Schnettler and Steinbach (2011) find that the stepgap in adolescents’ perceived parental closeness and care persists even after taking into account children’s age, other relevant factors that can vary within families, and, most importantly, after applying family fixed effects to control for

unobserved heterogeneity between families. Arránz-Becker et al. (2013) also find a persisting stepgap after inclusion of family fixed effects in their statistical models, in this case applied to parents' emotional closeness to their mostly adult children in Germany.

Both studies also reveal a number of moderating factors that narrow the stepgap. These are, most importantly, relationship duration, the amount of family resources, and the importance of norms of familism. Yet, in both studies, a considerable stepgap persists even after taking these moderating factors into account (Arránz-Becker et al. 2013; Schnettler and Steinbach 2011). Together, these studies thus provide evidence that unobserved heterogeneity seems not to be the sole explanation for the stepgap, at least with regard to the particular indicators studied. This is consistent with studies using fixed-effects models to control for unobservable factors across time, siblings, or families with regard to the effects of divorce. Here, too, a central conclusion is that effect sizes decrease after taking into account unobserved heterogeneity, but moderate associations between divorce and outcomes persist on a range of measures (Amato and Anthony 2014).

Different from the selection hypothesis, the stress mediation hypothesis attributes a causal role of family transitions (separation, re-partnering) to developmental outcomes for children and adolescents growing up in stepfamilies. Living in a stepfamily implies that the parents of a focal child or adolescent have at least once separated or divorced and formed a new relationship. According to the hypothesis, each family transition creates stress which can accumulate across multiple transitions and negatively affect developmental outcomes in those affected by these (multiple) stressors (Hadfield et al. 2018). An enormous amount of literature on the consequences of divorce shows that relationship instability and divorce can harm development in manifold ways and with persistent, adverse effects into adulthood (Amato 2001; Amato and Anthony 2014; Patterson 2001). A recent review that covers 39 articles published over the preceding decade that specifically test the instability hypothesis also generally shows support for the

instability hypothesis. But mixed results with regard to certain transitions, groups, and outcomes point toward additional explanatory factors that may be at play but are not yet well understood (Hadfield et al. 2018, p. 20).

Recently, researchers in the social sciences have increasingly focused on the complexity of family constellations across households at a given time as one such overlooked factor (cf. Schnettler and Steinbach 2011, p. 190). One might argue that the specific family and household structure of a child adds another set of potential stressors that contributes to the link between family type and developmental outcomes. Navigating family relationships across households may be stressful merely because it is more demanding to organize life across two more or less geographically distant households than it would be to organize daily life in one household. In addition, communicating and negotiating the demands of the parent living in either household may be emotionally taxing, a challenge that arguably becomes more difficult as additional relationships are involved, e.g., toward stepparents and step-siblings in the main and secondary parental home. This reasoning may be used to extend the instability hypothesis toward an instability-complexity hypothesis: multiple family transitions and the degree of complexity of cross-household family constellations both provide independent and additive sources of stress that may cumulate and affect developmental outcomes of children and adolescents.

The Evolutionary Approach to Understanding Stepparental Behavior

In the standard social science approach, the stepgap is interpreted mainly as the consequence of various stressors stemming from characteristics of the family environment (see above). In contrast, sciences that explicitly draw on Darwinian evolutionary theory see evolved anthropological inclinations as the driving forces behind the stepgap. Kin selection theory (► [“Kin Selection”](#)) explains why biological children usually receive significant parental investment and why parents truly exhibit an interest in their children's

prosperity. For the same ultimate causes, that is, the absence of (personal or inclusive) fitness benefits, stepparents do not have kin-altruistic interests in their non-genetically related stepchildren. In general, parental investment can be understood as any kind of resource transfer from parents to their offspring. Parents usually do not receive economic or social net-benefits for taking over the tasks of parenting (Lee and Kramer 2004), but when investment occurs for biological offspring, altruistic behavior can increase direct fitness, also known as personal fitness.

In contemporary industrialized countries, step-parenting occurs most commonly due to parental separation or divorce. However, in historical Europe as well as in societies in Sub-Saharan Africa, stepparental relationships are mostly due to parental death (Bock and Johnson 2008). The tasks of parenting are then often taken up by adult kin, like grandparents, biological aunts, and uncles who adopt their grandchildren, nieces, or nephews. For these cases, inclusive fitness theory predicts that stepchildren receive more care and attention than stepchildren would do on average. This is because they are biologically related to their stepparents. However, due to their lower genetic relatedness and the absence of direct fitness benefits, the theory still predicts them to receive less care and attention, on average, than children would usually receive from their biological parents.

Whereas kin selection theory argues on the level of ultimate causality, there is also research on the proximate mechanisms that may be involved in mediating parental investment: It is expected that natural selection has favored such mechanisms that (a) increase the likelihood of having biological offspring, e.g., by means of sexual desire or an emotional desire to have children (cf. Foster 2000), (b) make adults attend and respond to the needs of infants (see ► [“John Bowlby and Attachment Theory”](#)), and (c) allow individuals to reliably recognize and to direct investment toward close biological kin (► [“Kin Recognition”](#)). The evolved proximate mechanisms therefore will reduce the likelihood that stepparental altruistic behavior is exhibited toward non-genetically related children.

When it comes to stepparental investment specifically, one central point of debate with regard to potential mechanisms has been the question as to whether the stepgap is merely the result of higher (step-)parental investment in favor of biological over stepchildren or whether stepparents actively disadvantage their stepchildren in the household. Research on this topic has been inspired by Daly and Wilson (1985, 1999) who were among the first to make an argument for the latter and to name the tendency toward disadvantaging stepchildren the “Cinderella effect,” alluding to Cinderella’s bad treatment by her stepmother in the fairy tale of the same name by Brothers Grimm. They supported their argument empirically with a study using data from the American Humane Association. Here, they compared the risk of fatal child abuse in households with and without the presence of a stepparent and showed that the risk was indeed higher in households where a stepparent was present. Although their foundational work in this area has provoked many, partly justified, methodological criticisms (see, e.g., Buller 2005), further research around the globe replicated Daly’s and Wilson’s finding, even after considering a variety of relevant context factors (e.g., Anderson et al. 1999a, b). In this regard, the sequence of events resembles that in the social scientific literature cited above. Yet, the interpretation of results has been different: Whereas social scientists have tended to see the remaining stepgap as the result of yet unexplained contextual factors (e.g., hitherto unmeasured forms of stress in complex family and household constellations), evolutionary psychologists have interpreted the residual stepgap as a potential result of the “Cinderella effect,” and there has been a heated debate on whether this effect can be understood as an unconditional (“hardwired”) human trait.

The discussion of the “Cinderella effect” in Darwinian psychology has largely ignored potential variability in the origins of stepfamilies across time, place, and population segments. However, as we have already pointed out above, stepfamilies can be the result of divorce and remarriage. Or they can be the result of parental death and remarriage. In that case, the formation of a

stepfamily can indicate normalization after a severe family crisis (Anderson et al. 1996), whereas step-parenting due to divorce might indicate a family environment in which parental motivation to care is reduced and in which parents and children are exposed to a set of potential stressors (see above). Willführ and Gagnon (2013) illustrate the conditionality of parental motivations to invest in or even actively disadvantage their stepchildren. They investigated the consequences of parental death and remarriage in the historical Krummhörn region in Germany (1720–1874) and in the historical St. Lawrence Valley (1670–1799). In the Krummhörn region, the presence of a stepmother was associated with increased offspring mortality to a similar extent as the death of a mother, whereas the remarriage of the father was a neutral event for his children from a previous marriage. The differential effect of the stepmother can be explained by the different socioeconomic contexts: Although the population of the St. Lawrence Valley was expanding, individuals were competing less for an inheritance (e.g., the parental farm), as land was abundantly available for the French settlers who benefitted from large family sizes. In contrast, the Krummhörn region was demographically saturated and there is evidence for increased sibling competition. By disadvantaging the children of her husband's former marriage, the stepmother intervened for the benefit of her own children. The conclusion of this study is that a stepparent's behavior is conditional on socioeconomic context and depends on whether reproductive interests are narrowed by one partner's former reproduction.

Overall, we can understand the treatment of stepchildren as an expression of an opportunistic strategy which is characterized by a trade-off (cost-benefit calculation). This trade-off is dependent on the socio-environmental context: If the benefits for the stepparent prevail over the costs, stepchildren can expect to receive a certain amount of stepparental investment even if the stepparent does not have an altruistic interest in a stepchild's prosperity. An illustration for this trade-off in modern stepfamilies would be a case of overdue alimony payments by the absent biological parent. Depending on the amount of

financial resources in the newly formed stepfamily, overdue or withheld alimony payments by the absent biological parent may to a higher or lesser degree mean a financial burden for the stepparent and thus enhance conflict potential within this newly formed stepfamily.

Whereas much of the literature on parental investment in stepfamilies focuses on disadvantages, it is worth noting that stepparental investment is – under certain conditions – consistent with evolutionary theory. Although kin-selection theory predicts that stepparents are not altruistically interested in their genetically unrelated stepchildren because of the absence of fitness benefits, there may be other evolved motivations why stepparents display parental investment toward their stepchildren. One such case is when the motivation to invest may be part of a mating or mate-retention effort (Anderson et al. 1999a, b). Another case could be stepparental investment as a signaling effort, e.g., to earn reputation in one's social network in social contexts where stepparental investment is highly encouraged by social norms. Finally, if one considers that many individuals display a desire to have and care for children – a desire that itself may be an evolved motivation (Foster 2000; Rotkirch 2007) – step-parenting may be one way to fulfill this desire, especially for individuals unable to have biological children.

Conclusion

From this review of the literature on step-parenting, it becomes apparent that the (evolutionary) biological, psychological, and social scientific literature focus on different aspects of step-parenting. Whereas both the evolutionary and social sciences have empirically established the stepgap and then shown that it gets smaller with better methodological designs and better data, they have highlighted different potential explanations for the remaining stepgap. Evolutionary biology and psychology aim at explaining different motivations for parents to invest in their biological children and stepchildren. The social scientific literature,

however, has focused mainly on explaining the stepgap by means of contextual factors like family resources and stressors across different family types. We argue that these approaches are not necessarily at odds with each other but complement each other in central aspects. In order to integrate them we need to engage with these various theories on a more fine-grained level and build new, interdisciplinary models that integrate motivational and contextual factors. Also, new types of data collection will be necessary that combine contextual variables along with biologically relevant variables. Human life courses are neither solely affected by evolved inclinations and individual motivations nor are these anthropological inclinations hardwired to a degree that makes them unmodifiable to environmental influences.

Non-biological parents

Definition

An adult person (man or woman) becomes a stepparent if he/she lives together in a romantic relationship (e.g., marriage) with a partner

who already has one or more biological children from a previous relationship. Stepparents must be differentiated from adoptive parents, as the latter raise children who are not biologically related to any of the two parents.

Introduction

The possibility of becoming a stepparent is not exclusive to people in modern societies. In some bird and primate species (e.g., olive baboons), it has also been observed that a new partner helped raise the offspring of a female (Rohwer 1986; Smuts 1985, cited in Anderson 2011). Even in pre-industrial societies many families exist in which children live together with the mother and her new partner after the father's death or when the parents' relationship ends for any other reason. In the Middle Ages in Western societies, stepmothers were more prevalent because of the common remarriage of fathers after their wives' death due to perinatal complications. In today's Western societies, in contrast, the number of stepfathers significantly exceeds that of stepmothers. The reason for this is that after divorce children usually stay with the mother. Some calculations show that 30% of American children live with a stepparent, typically with a stepfather (Bumpass et al. 1995, cited in Anderson 2011). This rate in Europe varies between 1.1% and 11.4% (Heuviline et al. 2003, cited in Anderson 2011).

Stepparents and Evolution

According to Miller (2001), in hominid predecessors of *H. sapiens* monogamous relationships lasted for a couple of years. After this period pairs split up and formed new exclusive relationships. In this mating pattern, also called *serial monogamy*, children usually stayed with the mother. However, mating behavior was combined with parenting behavior both in males and females. Partner choice of males was influenced

by their impression of maternal competence of available females, as a sign of their capability to care for the males' future offspring. Similarly, hominid females with an offspring paid attention to potential mates' willingness to cooperate in child raising and probably were influenced by the attraction of their children toward these males as well. Female partner choice, therefore, was intertwined with children's choice. Nevertheless, the courting effort of hominid males was directed partly on the offspring of potential sexual partners. Hence the presence of children around reproductively active adults might have had a major effect on sexual selection.

Stepparents and Parental Care

The majority of stepparents not only tolerate but also support their stepchildren. At first sight this could seem a violation of *Hamilton's rule*. However, in light of the above evolutionary considerations, this behavior is reasonable. Stepfathers' willingness to invest in their stepchildren increases their attractiveness and enhances the quality and stability of the relationship between partners as well (Lancaster and Kaplan 2000). Nevertheless, not surprisingly, biological fathers invest more in their biological children than stepfathers all around the world. Biological children, in general, have an advantage over stepchildren. Stepfathers spend less time with their stepchildren, provide less financial support (Anderson et al. 1999a), and communicate and play less with them (Marlowe 2005). Studies with 5–12-year-old children showed that co-residence is also a significant factor of parental support (Anderson et al. 1999a, b). Stepfathers and biological fathers support children living in the same household to a similar extent, irrespective of genetic relatedness. Investment by stepfathers correlates positively with the time spent together in the family. Although some stepparents might have negative feelings toward stepchildren at the beginning,

there is a good chance that positive experiences will change these so that stepchildren will be treated similarly to biological ones (Marsiglio 1991).

Stepparents and Child Abuse

In contrast to the quite frequent occurrence of infanticide in the animal kingdom, human infanticide is relatively rare, although prevalent. Daly and Wilson (1985) showed that in those North American families where at least one of the parents is a stepparent, the likelihood of child abuse is 30–40 times higher than in families where all members are genetically related. In the case of infanticide, this figure is 70–100 (Daly and Wilson 1994). Regarding the way of perpetration, it was found that biological fathers choose a quicker and less painful method of murder. This holds for the difference between stepmothers and biological mothers as well (Weekes-Shackelford and Shackelford 2004).

Conclusions

The presence of a stepparent in the family might have been a frequent feature of the environment of our hominid ancestors. Even though the enhancement of inclusive fitness is considered a major goal in evolution that affects allocation of resources and competition among conspecifics, sexual selection might divert individual strategies from focusing only to direct reproductive benefits. Serial monogamy, for instance, creates circumstances under which parenting effort directed toward genetically unrelated juveniles is in fact not only beneficial but downright necessary in terms of reproductive fitness. Thus, the behavior of human stepparents is characterized much less by causing disadvantages to stepchildren, and more by showing the same amount of care as for biological relatives, than it is typical in other animal species.

Stereotyped vocalization: Evolved, species-typical vocal act with signal character.

Introduction

How did human communication evolve from an animal-like vocal system to spoken language? Research on primate communication in particular has produced a wealth of data, which highlight the various evolutionary continuities and discontinuities between animal and human communication. Research topics include the mechanisms and flexibility of sound production, how different call units are assembled into complex utterances, how meaning is extracted from vocal structures, and how the psychological mechanisms underlying animal call production and comprehension

compare to those of humans. The purpose of this chapter is to present the state-of-the-art of these various strands of research and to show how methodological tools of linguistics can help decipher animal communication.

Animal Vocal Behavior

Vocal Control

Mammalian vocalizations are produced by a larynx that oscillates in response to airflow from the lungs. This creates a basic acoustic signal further shaped by the supra-laryngeal vocal tract. Many species can actively change the geometry of their vocal tracts, which determines the call's resonance properties and acoustic quality. Within the primates, humans are somewhat special in that the larynx is in a permanently low position, which results in a characteristic perpendicular two-tube vocal tract. There has been much debate as to whether this anatomical specialization is crucial for speech production, but current opinion suggests that this is not essential. Humans are also unusual in their high degree of motor control of both larynx and vocal tract, mostly due to specialized cortical innervations (Ackermann et al. 2014). Great apes also have relatively good motor control over the facial musculature, including some of the speech articulators, suggesting that the transition to speech was largely due to control of the larynx (Lameira et al. 2014). One consequence of the lack of voluntary control over sound production is that nonhuman primates are essentially prevented from acquiring new sound patterns by vocal learning. As a result, each species communicates by means of species-specific vocal repertoires that develop under relatively strong genetic control.

Acoustic Flexibility in Animal Calls

Although the differences to humans are vast, primates exhibit limited vocal flexibility in some call types. At the most basic level, many call types carry individual signatures, which enable receivers to extract identity information. For

example, chimpanzees (*Pan troglodytes*) recognize each other by their pant hoot vocalizations, a long-distance signal, and discriminate the calls of neighboring males from the calls of unknown stranger males (Herbinger et al. 2009). Another interesting example is found in bottle-nosed dolphins (*Tursiops truncatus*) where individuals match each other's individual signature whistles, although they are not produced by the larynx (King and Janik 2013). Although there is widespread evidence for individually distinct calls, not all call types convey identity cues, Gelada baboons (*Theropithecus gelada*) being a striking example (Bergman 2010). In several primates, there is also evidence for acoustic convergence, usually within the contact calls. The general pattern is that calls of closely affiliated individuals are more similar to each other than calls of less affiliated group members. Another source of acoustic flexibility is found in calls given to external events as, for example, in Japanese macaque (*Macaca fuscata*) and chimpanzee food calls, Rhesus macaque (*Macaca mulatta*) and chimpanzee agonistic calls, or baboon (*Papio ursinus*) alarm barks (Zuberbühler 2015). A related but somewhat more complex way of creating acoustic variation is by assembling discrete acoustic units within the same calls. For example, male Campbell's monkeys (*Cercopithecus campbelli*) combine three basic alarm calls with an acoustically invariable vocal suffix. Suffixes are typically given to situations that do not warrant direct or strong antipredator responses, while unsuffixed calls are almost always given to dangerous predators, such as leopards or crowned eagles. Diana monkeys (*Cercopithecus diana*), a frequent association partner of Campbell's monkeys, discriminate this subtle feature, suggesting that suffixation is an evolved function in primate communication. Another relevant example is Diana monkey contact calls, which consist of individually distinct arched structures that convey identity information, which are regularly combined with three other call types linked with specific external events (Zuberbühler 2015).

Animal Call Sequences

In a number of species, semantically relevant units can be at the level of call sequences, rather than individual calls (Kershenbaum et al. 2016). A recent example is the vocal system of pied babblers (*Turdoides bicolor*), a social passerine that combines alert and recruitment calls into sequences when encountering terrestrial predators. Recipients respond differently to sequences than components calls, and it has been argued, controversially, that these birds show compositionality, as they communicate both context and requested action (Engesser et al. 2016; but see Schlenker et al. 2016). Related examples in primates are the call sequences of black-and-white Colobus monkeys (*Colobus guereza*), with sequence length and structure relating to predator type. In putty-nosed monkeys (*Cercopithecus nictitans*) call combinations encode both predator class and travel intention and in Campbell's monkeys predatory and non-predatory dangers (Schlenker et al. 2016). For apes, gibbon duet songs broadcast social information relevant to neighboring individuals but lar gibbons (*Hylobates lar*) also sing when encountering predators. Predator-induced songs and duet songs are assembled from the same unit repertoire but according to different patterns. Another example is bonobos producing sequences of acoustically variable calls when finding food, which are linked to the value of the food, something that listeners use to base their foraging decisions (Zuberbühler 2015).

Meaning in Animal Calls

There is overwhelming evidence that primates can extract information from others' calls, sometimes by taking into account the pragmatic context or reason for calling. The basic pattern is that specific events tend to trigger specific vocal responses, which are recognized and interpreted by listeners, a sort of by-product semantics. Hence, one hypothesis is that there is a profound discrepancy between signalers (uttering vocalizations for specific functions, e.g., to recruit a nearby ally), and recipients, who can infer the call causing events, even if not participating in the event. According to this model, nonhuman primate communication is

profoundly different from human language, where speakers are interlinked at a deep psychological level. Humans communicate, verbally or nonverbally, to be understood and have repair mechanisms in case of failure. Recipients, on the other hand, assume that signalers intend to communicate something meaningful and use common ground to infer meaning, beyond signal-event contingencies and direct linguistic meaning. An important problem in current research is therefore the degree to which primates communicate "intentionally," i.e., with the goal of informing about events relevant to their listeners and whether they experience an intention to be understood.

Recent research on call meaning has focused on three main questions: (i) what is the referential content or meaning of individual calls? (ii) How are the meanings of individual calls combined? (iii) Is the meaning of calls sometimes enriched by "pragmatic" principles of competition, notably an "informativity principle" whereby a more informative call is preferred whenever possible over a less informative one?

Campbell's monkeys afford a rich case study (Schlenker et al. 2016). Males use a call *krak* to raise leopard alerts and *hok* for raptor alerts, as well as suffixed *krak-oo* for alerts of all sorts and *hok-oo* for non-ground alerts. The challenge is to assign meanings to *krak*, *hok*, and *-oo*. Further complexity is added by Campbell's call use in another habitat, Tiwai Island, Sierra Leone, where leopards have not been seen for decades. Although both monkey populations produce the same call types, there are relevant differences in call use. On Tiwai, *krak* raises unspecific alerts (as does *krak-oo*), rather than specific leopard alerts, possibly a case of limited "dialectal" variation: *krak* has a leopard meaning in Tai and a general meaning on Tiwai. On an alternative theory, the "informativity principle" plays a key role: *hok* has a meaning of aerial alert, and *-oo* weakens the resulting alert, hence *hok-oo* is used for non-serious aerial alerts. *Hok* is further enriched by competition with the (more informative) call *hok-oo*, which explains why *hok* comes to be used for serious aerial alerts – hence raptors. *Krak* has a meaning of (general) alert at both sites, hence *krak-oo* is used for nonserious alerts.

By the “informativity principle,” the meaning of *krak* is further enriched by competition with *krak-oo* (“there is a nonserious alert”) and *hok* (“there is an aerial alert”). In the end, *krak* can only be used for *serious (not krak-oo) ground (not hok) disturbances* – hence the leopard uses in Tai. On Tiwai, the “informativity principle” would yield a useless meaning due to the absence of serious ground predators, hence *krak* retains its basic meaning.

The debate on the meaning of Campbell’s calls is still open, but several species might provide independent evidence for the “informativity principle.” Often calls are used in highly heterogeneous contexts and seem to have a general alert meaning; but in the event of a specific threat for which there is a precise call the more informative call trumps the general one.

Concerning call combination, a key question is whether call sequences are “compositional,” which is the case if *their meaning can be systematically derived from that of their parts*. As mentioned, in black-and-white Colobus monkeys, putty-nosed monkeys, and titi monkeys, some sequences seem to be interpreted “wholesale” and thus to present challenges to compositionality. Three general research directions are currently explored (Schlenker et al. 2016): (i) some call sequences might indeed be irreducible to the meaning of their component parts (possibly in Colobus and putty-nosed monkeys); (ii) sometimes a compositional analysis can be maintained if call meanings are taken to be very weak, and to be enriched by some competition principles; (iii) sometimes the complexity of the call sequence might reflect the caller’s changing perceptions as the events unfold.

Intentionality in Animal Communication

In great apes, there is evidence that signalers are aware of the social consequences of some of their signals, but there is no strong evidence that they also actively inform others or take their mental states into account during call production. Signal production may be based on simple social categories, such as dominance or affiliation, rather than the shared history with individual recipients and their momentary mental states, such as knowledge or ignorance. Although primates can perceive

others as goal-directed agents, they may not consider their mental states, such as beliefs or knowledge, when addressing them. Related to this, primates are not generally motivated to use communication in a cooperative way to inform others about facts or events relevant to them. Noteworthy exceptions are studies on predator encounters where signalers, especially adult males, appear to be concerned about the wellbeing of others (Zuberbühler 2015). Other forms of seemingly altruistic signaling, such as when encountering food, can be explained by callers trying to avoid negative consequences if failing to advertise the event.

Conclusion

Many social animals, including humans, possess a repertoire of species-specific vocalizations, with different calls produced to more or less specific events. However, humans have evolved an additional layer of vocal control, characterized by highly coordinated movements of the jaws, lips, and tongue in union with controlled laryngeal sound production. Nevertheless, recent work on nonhuman primate calls has shown some acoustic flexibility within individual calls and also at the level of call sequences.

The default model is that animal signals serve evolved biological and social functions, e.g., to dissuade predators, to recruit others, or to induce competition for copulation calls, but these contingencies are readily absorbed and actively interpreted by listeners, a sort of by-product semantics. Several studies have further shown that receivers attend to subtle acoustic variation within some call types in ways that suggest that they are meaningful to them. Progress has also been made by applying linguistic theory to the study of primate call sequences, in particular to assess the respective roles of call meaning, principles of call combination, and potential rules of competition among calls.

Another major theme in animal communication is whether nonhuman individuals produce signals with an intention to inform others. Here, the evidence is relatively weak, with only a

handful studies suggesting that callers monitor whether others have perceived or understood their signals or show concern to provide information that is relevant for their recipients. Studies on ape gestural communication, however, suggest that basic mental state attribution is within the cognitive realm of primates and can play a role in communication.

To conclude, although differences are vast, human vocal communication, including spoken language, is the result of evolutionary continuity with relevant precursors seen in nonhuman primates in almost every relevant capacity.

Definition

Sexual signaling refers to the ways that members of one sex signal their mate quality to members of the opposite sex.

Introduction

Steve Gangestad, Distinguished Professor, Evolutionary-Developmental Area Head University of New Mexico, is a psychologist at UNM, where he is best known for his work on evolution and development using quantitative methods. For many years he has been working with collaborators – notably Randy Thornhill – on the question of whether, in humans, female estrus is (as some scholars aver) truly lost. Typically, primates advertise their fertile phase through conspicuous displays. Humans do not do this. However, Gangestad has argued that a raft of behaviors indicate that estrus is concealed in humans rather than lost. This implies that there are two distinct types of sexual behavior in women. The first, during the fertile phase and the second – extended sexuality – during the non-fertile phase. Humans are not unique in having sex outside of fertile phases (bonobos and cetaceans also do this Gangestad et al. 2015), and Gangestad's work aims to root the study of human sexuality within the general phylogeny of vertebrates (Thornhill and Gangestad 2008).

Sexual Hide and Seek

For organisms to be able to transmit mate quality to potential partners in ways that might fall under selection (intra-sexual selection), it must be a hard to fake signal. There are a variety of ways for members of a species to honestly signal their quality to potential mates (Zahavi 1975; Gangestad and Thornhill 1997). Using peer report of attractive qualities in others, rather than the more usual self-report, Gangestad (Speed and Gangestad 1997) showed that sexually popular males are physically attractive, seen as trendsetters, and outgoing. Attractiveness in females also emphasized physical attraction and trendsetting. Surprisingly, earning potential did not feature in this population as a marker of attraction.

While all cultures value facial attractiveness, it is not immediately obvious why this should be. If such attraction were an entirely capricious thing, then it would imply that such qualities do not reliably covary with any underlying features in

potential mates. This is unlikely. Gangestad's work has shown repeatedly that in general, healthy mates are preferred and indicators of such things (such as clear skin and eyes and lustrous hair are universally valued (Thornhill and Gangestad 1999a)). Facial symmetry also seems to be a marker of genetic quality given that such symmetry reliably indicated resistance to developmental pathogens that would have resulted in asymmetry over evolved time, although the support for this hypothesis is more mixed.

Smell also indicates partner quality, perhaps in terms of compatibility. While human males seem largely unaware of the importance of this marker, human females regularly report that partner general attractiveness and partner smell covary (Thornhill and Gangestad 1999b). Indeed, an attractive partner smell was the leading predictor of orgasmic response in females – which may contribute to fertility (Thornhill and Gangestad 1999b; King and Belsky 2012). It is, however, unclear as yet as to whether attractiveness in partner smell results from an honest signal of general quality (e.g., that attractive scent covaries with symmetry) or signals specific major histocompatibility between the sexual partners. That the incidence of female orgasm seems to increase with extra-pair copulations, lends credence to the view that there is a sperm-selection function at work.

As noted above, a standard textbook view has been that human female primates are unique in having concealed ovulation. One of the figures chiefly responsible for revising this view has been Steve Gangestad. As he has shown in a variety of ways, it is more appropriate to think of ovulation as being guarded rather than completely covert. Not only does women's behavior become more overtly sexual and assertive during their fertile phase, but their partners seem alert to this on some level, increasing their levels of mate-guarding behaviors (Thornhill et al. 1995; Gangestad et al. 2014).

Conclusion

It is trivially true to say that humans are a unique species – uniqueness is built into the definition of a species. However, some mistake uniqueness for

immunity to the normal rules of natural and sexual selection. Gangestad's (and others) work on sexual signaling shows that humans are complex sexual strategists – just like any sexually reproducing species. Furthermore, he has shown that attention to evolutionary theory generates a range of falsifiable hypotheses about human behavior. For example, it is still an open question whether general symmetry (indicating developmental stability and hence immunocompetence) or specific markers of histocompatibility are being signaled in terms of mate preference. This alone gives the lie to oft-repeated canard that evolutionary hypotheses are fundamentally untestable. On the contrary – humans are rapidly being shown to have a range of complex strategic responses to mate selection utterly in keeping with their evolved natures.

Steven Pinker

Ava Kiai

Department of Cognitive Studies, École Normale Supérieure, Paris, France
Max Planck Institute for Empirical Aesthetics, Frankfurt am Main, Germany

Steven Pinker (1954–) is a Canadian-American experimental psychologist and public figure. He is considered one of the most influential living figures in science and a leading expert on language and the mind.

He is known to general audiences as the author of numerous books ranging in subject from the mind and brain to human nature, violence, and language, including *The Language Instinct: How the Mind Creates Language* (1994), *How the Mind Works* (1997), *The Blank Slate: The Modern Denial of Human Nature* (2002), and *The Better Angels of Our Nature: Why Violence Has Declined* (2011).

Pinker is the Johnstone Family Professor of Psychology at Harvard University. Until 2003, he taught at the Massachusetts Institute of Technology, serving also as Director of the McDonnell-Pew Center for Cognitive Neuroscience (1994–99) and earlier as Co-Director of the Center for Cognitive Science (1985–84). He frequently appears on public debate panels (2005) and discussions and writes for numerous publications including *The New York Times*, *The Atlantic*, and *Time* magazine.

Education and Research on Visual Cognition

Pinker received his Bachelor of Arts in experimental psychology from McGill University (1976) before earning his doctorate from Harvard University (1979). Pinker's doctoral research, carried out under the supervision of Stephen Kosslyn, focused on visual cognition and the mental representation of objects in three-dimensional space.

Research on Language

Pinker completed his postdoctoral fellowship at MIT under the mentorship of linguist Joan Bresnan, previously a student of Noam Chomsky. This and subsequent research led to the publication of two technical texts: *Language Learnability and Language Development* (1984), in which Pinker presents a theory of how children acquire words and grammatical structures; and *Learnability and Cognition* (1984), focusing on syntax and the behavior of words, notably verbs, as well as the implications of these findings for our understanding of how the mind represents language.

In 1994, Pinker published *The Language Instinct*, in which he argues for the innateness theory of language. Inspired in part by the work of linguist Noam Chomsky, *The Language Instinct* presents wide-ranging evidence from cognitive neuroscience, developmental and experimental psychology, and linguistics for the theory that the ability to acquire grammar and new words is innate.

For both Pinker and Chomsky, the common logic underlying the world's languages, and the surprising speed and skill with which children acquire their native language, learn the meanings of words, and generalize grammatical rules are all evidence in favor of a universal grammar. Indeed, nearly every sentence a child hears or speaks is a unique arrangement of words; language must therefore be represented in the mind as a discrete combinatorial system, where a finite number of units can be combined in an infinite variety of ways. Universal grammar would explain the

“linguistic genius” demonstrated by children when faced with such an overwhelming influx of information.

Pinker moreover asserts that the apparently unique existence of the language faculty in modern humans can be explained with the Darwinian theory of evolution and natural selection.

In later books, notably *The Blank Slate*, Pinker applies the view that humans are born with certain innate cognitive capacities to human nature and cognition more broadly, opposing the notion of the “blank slate,” whereby the mind is a general-purpose learning machine, and human nature is purely a product of the individual's environment.

Pinker further discusses the mental representation of language and elements of language, such as word origins and word structure, in *The Stuff of Thought* (2008) and *Words and Rules* (1999).

Research on Violence

In his 2011 book, *The Better Angels of Our Nature*, Pinker argues that we are living in perhaps the most peaceful period in human history. He presents evidence that violence of all kinds has declined since our prehistory, drawing on extensive data drawn from research in the social, political, and historical sciences, as well as from cognitive science.

Pinker lists six major movements in the decline of violence:

1. The Pacification Process, in which nomadic communities formed agricultural societies, which grew into the first nation-states.
2. The Civilizing Process, in which rulers consolidated smaller, belligerent, feudal territories into larger kingdoms and commercial, cosmopolitan, and industrial forces incentivized peaceful exchange between members of the society.
3. The Humanitarian Revolution, exemplified by the eighteenth- and nineteenth-century European Enlightenment, and notable for major advances in secularism and humanitarianism. This era saw the widespread abolition of judicial torture, capital and corporal

punishment, slavery, and other previously state-sanctioned cruelties.

4. The Long Peace, or the unprecedented decline in warfare and violence since the end of World War II.
5. The New Peace, the further decline in organized conflict since the end of the Cold War in 1989.
6. The Rights Revolutions, the multiple civil, women's, children's and animal rights movements in the twentieth and twenty-first centuries that lowered our tolerance for hate crimes, domestic violence, child abuse, and animal cruelty.

According to Pinker, the exogenous causes of these historical trends can be attributed first to the rise of nation-states and the consolidation of power in centralized governments. Borrowing from Thomas Hobbes's political philosophy, he calls this the "Leviathan": as states gained a monopoly on the legitimate use of violence, levels of violence between individuals decreased.

Second, the rise of commerce incentivized cooperation and communication between individuals, rendering one's trading partners more valuable alive than dead. The zero-sum game of plunder thus gave way to the positive-sum game of trade.

A third factor is what Pinker calls the "Escalator of Reason," in which a confluence of events, such as the advent of the printing press and the consequent of the growth of literacy, as well as technological innovations that facilitated travel and the sharing of information between distant places and peoples raised general awareness about the world, lowered belief in superstitious doctrines, and encouraged the flourishing of rational thought. Together, these forces rendered practices such as witch-hunts and heresy trials, as well as torture and slavery less and less justifiable.

Lastly, Pinker argues that reasoning about the common experience of pleasure and pain, the discovery of the mutual benefits of nonviolence and other forms of cooperation, and repeated interaction with other groups widens the circle of people for whom we feel empathy or concern. Borrowing from philosopher Peter Singer, Pinker

calls this concentric form of moral progress the "Expanding Circle."

On Writing

Pinker has expressed criticism for traditional style manuals which impute arbitrary rules of language use that "force writers into fuzzy, clumsy, wordy, ambiguous, incomprehensible prose, in which certain thoughts are not expressible at all" (2007). In 2014, Pinker published his own style guide, *The Sense of Style: The Thinking Person's Guide to Writing in the twenty-first Century* (2014).

Awards

Pinker has received numerous awards for his scientific research, as well as for his books. In 2016, he was nominated to the National Academy of Sciences. He has also received awards from the American Psychological Association, the National Academy of Sciences, and the Royal Institution in Great Britain.

Definition

A description of Steven Pinker’s scholarly work on language development and psycholinguistics.

Introduction

Steven Pinker was born in Montreal, Quebec, Canada, in 1954 and is a prominent psychologist, linguist, and professor in the Department of Psychology at Harvard. He is well-known as a popular science author and an advocate for science, especially evolutionary psychology (for which he won the Richard Dawkins Award in 2013). He is also a major proponent of the information processing metaphor of the mind and frames human language development in terms of evolved psychological mechanisms operating like software on the hardware of the physical brain.

Pinker’s published research on psycholinguistics is highly influential. For instance, a 1988 paper challenging the popular connectionist theory of regular and irregular phenomena in language (Pinker and Prince 1988) has over 1900 citations to date.

He has also written major review papers on language development processes (e.g., Pinker 1979). Additional areas in which Pinker has contributed to our knowledge on language development include the neurological bases of grammar, the use of euphemism, irony, and innuendo. He has written two technical books that proposed a general theory of language acquisition and applied it to children’s learning of verbs.

In several books written for a mass audience, Pinker has provided a litany of evidence, from both his own original research and from the field of psycholinguistics more broadly, regarding the existence of innate mental modules for language acquisition shaped by natural selection. Of his seven books, six include psycholinguistics as a primary or major theme: *The Language Instinct* (1994), *How the Mind Works* (1997), *Words and Rules* (1999), *The Blank Slate* (2002), *The Stuff of Thought* (2007), and *The Sense of Style* (2014). Pinker’s other book, *The Better Angels of Our Nature* (2011), reviews myriad evidence of exponential decline of violence per capita over millennia, centuries, and decades, and he suggests six major causal factors that explain this decline.

The following sections outline some of the key points of each of Pinker’s other six books, especially in regards to psycholinguistics and language development.

The Language Instinct (1994)

In *The Language Instinct*, Pinker asserts that the human capacity for language acquisition is innate. In many ways, Pinker agrees with Noam Chomsky’s theory of universal grammar, which states that language is hard-wired in the brain; that language skills develop naturally without instruction, rewards, or punishments; and that properties shared by all human languages demonstrate that it is a universal human trait. He does, however, consider himself more credulous than Chomsky regarding the ability of the theory of evolution by natural selection to explain our innate language capacities.

Pinker refutes purely behavioristic conceptions of language acquisition. For instance, Pinker

illustrates that children learn a great deal about language without instruction, which he claims is at odds with common conceptions of language learning. In addition, he criticizes common assertions that the typical person has poor grammar and that language is degenerating over time. He also provides evidence against certain academic linguistic theories such as the Whorfian Hypothesis (also known as linguistic relativity), which states that the properties of a specific language affects how its speakers can perceive and talk about the world. He is especially critical of the “strong version” of this hypothesis: that language determines thought. For instance, one could claim, based on the strong version of the Whorfian Hypothesis, that a speaker whose native language has no word for “rebellion” would be able to express or perhaps even have thoughts of rebellion. Pinker argues in *The Language Instinct* that thought is independent of language and asserts “the more you examine Whorf’s arguments, the less sense they make” (p. 60).

Pinker views language as unique to humans and as an ability that allowed our ancestors to adapt to selection pressures whereby hunter-gatherers who could more effectively communicate with each other would have a survival advantage over those who could not. And because language capacity evolved as the result of a domain-specific selection pressure, Pinker asserts that it is a unique mental module rather than a component of a more domain-general skill such as general cognitive ability. Research supports such a view by demonstrating a double dissociation between brain injuries resulting in loss of language abilities and those resulting in loss of general cognitive ability (e.g., Dunn and Kirsner 2003). For example, a condition known as Specific Language Impairment results in impairment of language skills without impairment of cognitive ability (van der Lely 2005), and a condition known as Williams Syndrome results in impairment of cognitive abilities but not a direct impairment of language (e.g., Bellugi et al. 1988).

That language is a product of natural selection and an innate part of human nature means that it is not the direct product of human culture; it is not a human invention in the same way as the wheel or

the computer. Language is universal across all human cultures whereas human inventions are not. Pinker asserts that the universal sequence of language acquisition – wherein children first demonstrate language through babbling, then holophrases (single words expressing an entire thought), and other intermediate stages before, achieving mature language skills – is apparent even in deaf individuals. He cites research evidence of “manual babbling” (babbling with hand gestures) in deaf infants (e.g., Petitto and Marentette 1991).

Additionally, Pinker points to so-called critical periods in language development (age ranges during which a child must have a certain experience in order for language skills to develop normally) such as those detailed by Kuhl et al. (2003). Such specialized and rapid learning processes are not explainable by operant conditioning or formal instruction.

Pinker claims that these findings as well as the natural development and acquisition of language skills in the absence of formal instruction are indicative of the innateness of spoken language.

How the Mind Works (1997)

The Language Instinct: How the Mind Creates Language (1994) played a vital role in refuting many myths regarding the development of language abilities. Pinker argued against the behaviorist perspective that language acquisition was primarily or entirely the result of operant conditioning process and presented substantial evidence to attest to the fact that, despite its complexity, understanding and using spoken language is a relatively easy accomplishment for most children. Language acquisition is largely dependent on evolved psychological mechanisms, which result in a predictable developmental sequence of language abilities.

In *How the Mind Works* (1997), Pinker extends his work on language from *The Language Instinct* while simultaneously broadening the focus to include myriad other areas of psychology and cognitive science: vision and the senses, emotion and affect, ideology, sexual attraction and love,

gender roles and identity, learning, judgment and decision making, social behavior, and much more. Pinker's expansion of his range of topics is necessary to address the goal of *How the Mind Works*: to attempt to explain the many functions of the mind, including those that are poorly understood, in evolutionary terms. Or, as Pinker himself puts near the end of his book, "To get you to step outside your own mind for a moment and see your thoughts and feelings as magnificent contrivances of the natural world rather than as the only way that things could be" (p. 563). The work is largely inspired by and uses the frameworks of cognitive psychology and evolutionary psychology, and Pinker highly utilizes the work of prominent evolutionary psychologists such as John Tooby and Leda Cosmides.

Pinker's two main assertions in *How the Mind Works* are taken from cognitive and evolutionary psychology. First, Pinker utilizes the information processing metaphor from cognitive psychology/cognitive science, which posits that the human mind is like a computer, which utilizes sets of algorithms ("modules" or "programs") to process data and produce behavioral output. Second, Pinker asserts that these mental programs represent evolved psychological mechanisms that were crafted by natural selection to efficiently solve specific adaptive challenges: acquiring language, choosing mates, avoiding danger, etc. Pinker even uses an evolutionary framework to explain negative emotional states such as sadness, which may elicit social support when we need it most, and disgust, which motivates us to avoid contamination by potentially lethal pathogens. Because natural selection results in evolved psychological mechanisms that on average improve the odds of an organism passing on its genes, Pinker's viewpoint explains why our minds are often predisposed to believe things that are untrue but that enhance our ability to survive and reproduce.

Towards the end of *How the Mind Works*, Pinker poses the question "[I]f the mind is a system of organs designed by natural selection, why should we ever have expected it to comprehend all mysteries, to grasp all truths?" (p. 563) Indeed, a mind that evolved to efficiently navigate the

relatively small-scale social dynamics and primitive survival pressures of our early human ancestors should not be expected to easily grasp macroeconomics, geopolitics, or the mysteries of the cosmos.

Words and Rules (1999)

In *Words and Rules* (1999), Pinker uses a single phenomenon, the form and frequency of grammatical errors, and analyzes it from as many angles as possible in order to make a more general point regarding the nature of language and mind. His analysis provides evidence for his view of language development as emerging from evolved psychological mechanisms.

The title of the book refers to how Pinker contends language is organized in human minds. He states that words in our "mental dictionaries" are sometimes stored as unique semantic entries, but that others are constructed using morphological rules. For instance, once a child learns the basic rules for creating plural forms of nouns or the past tense of a verb, they would not need to create new mental dictionary entries, so "horses" and "baked" would be created and stored as extensions of "horse" and "bake," respectively without the creation of unique semantic entries. However, this sometimes leads to mistakes when a word has an irregular pluralization (e.g., "deer" rather than "deers" and "geese" rather than "gooses") or irregular conjugation (e.g., "swam" rather than "swimmed" and "built" rather than "builded"). Pinker thinks that forms of irregular verbs must be memorized directly rather than automatically connected to their present tense forms.

The Blank Slate (2002)

In *The Blank Slate*, Pinker argues more broadly against the misconception that human beings are "blank slates" or tabula rasa that are born without any innate predispositions. This involves again referring to his findings and the findings of other psycholinguists demonstrating innate learning mechanisms for language acquisition.

The Stuff of Thought (2007)

In *The Stuff of Thought* (subtitled: *Language As a Window into Human Nature*), Pinker examines the ways in which our words and thoughts are associated both with each other and to our experience of the world around us and again utilizes language to explore human nature and innate predispositions.

One major focus in the book is Pinker's assertion of the two things that language must do: (1) communicate a message from speaker to audience and (2) establish, preserve, or negotiate the nature of the relationship between the speaker and the audience. Because of this, we often observe differences between the surface meaning of an expression and its deeper meaning. For instance, common expressions such as "If you could keep the music down, that would be great" function as requests even though no overt request (e.g., "Would you please keep the music down?") or demand (e.g., "Keep the damn music down.") is made. It also serves to avoid sending the message that the requester is in a position of authority over the other person as a direct demand would and is thus perceived as more polite. Pinker explains that on one hand, the requester does indeed want something, while on the other you do not want to be perceived as bossing other people around, so you end up uttering a sentence that sounds like a hypothetical musing or like complete nonsense, but it functions effectively as a request and as a social negotiation.

The Sense of Style

Pinker's seventh book, *The Sense of Style* (2014), is a guide to writing nonfiction with a style that is appropriate for producing maximum comprehension in general audiences. Using evidence from psychology and cognitive science, Pinker explains why much of today's popular science writing is difficult for readers to understand and offers his own advice for how to avoid such pitfalls.

Conclusion

Stephen Pinker's work on language development includes both compelling original research as well as perhaps the best examples of summarizing the nativist approach to language for a general audience. In addition, his work integrates nativist theories on language into broader examinations of evolutionary psychology.

Steven Pinker on Genetic Determinism

Destiny Cunic¹ and Kevin Bennett²

¹Pennsylvania State University, Beaver Campus, Pittsburgh, PA, USA

²Department of Psychology, Pennsylvania State University, Beaver, Monaca, PA, USA

Synonyms

[Biological determinism](#)

Definition

Genetic determinism is an emerging idea in the genetic field that suggests that there are genetic predictors for behavior traits.

Introduction

Experimental psychologist Steven Pinker volunteered to submit his DNA to kick off George Church's Personal Genome Project (P.G.P.). The P.G.P. sought to create an online database of 100,000 people's genomes and traits to allow global engagement of geneticists. Pinker explains that increased interest in globalizing genetics and making access greater is leading to a rise in consumer genetics. Consumer genetics refers to commercially available genetic testing that can explain who each person is via their own genetic code. These genetic kits can vary in depth of information and offer consumers data on their ancestry, traits, and disease risk (Pinker 2009).

Benefits

Personal genomics allows everyday people to access information about their disease risk and other health factors. This information could lead to a future of personalized medicine with regimens and drugs that are established based on a patient's individualized gene code and needs, thus reducing the need for trial and error testing or prevention screening. The information would also shift the healthcare debate in a direction toward national health insurance by changing the way we view preexisting conditions and how insurers cover them, along with how customers purchase insurance plans (Pinker 2009). Additionally, by being knowledgeable of genetic history, individuals can make informed choices regarding the risks of passing along hereditary diseases during reproduction.

Understanding one's genetics also allows for greater understanding of one's personality. Genetic makeup plays a huge role in understanding what shapes a person beyond their environment. The variations in human genes are inevitably what causes human behavioral traits, which explains why people who are biologically related are more similar than unrelated people. This can especially be seen in instances of biological versus adopted siblings. The intensity of this similarity can also be seen in identical twins compared to fraternal twins or siblings, where identical twins with identical genetic makeup are much more similar in personality than twins or siblings that share only related genetic makeup according to Pinker (2009). Furthermore, understanding the underlying genetic causes of personality will allow greater understanding of how environment affects personality in comparison (Pinker 2009).

Genetic Determinism of Psychological Traits

Neuroscience and genetic testing express the link between genetic makeup and psychological traits such as intelligence. Genetic predisposition for certain levels of intelligence can be seen when

comparing identical twins raised together or that were separated at birth (Pinker 2006). The possible explanation for why humans differ in intelligence is mutation-selection. Unlike personality, where different personality traits have different values in society, higher intelligence is universally valued. Intelligence is also made up of a wide network of brain areas, along with physical well-being and health, and thus is dependent on a wide variety of genes that can be affected by mutation. These mutations may, in turn, cause decreased levels of intelligence (Pinker 2009).

Genetic testing can be used to determine how dopamine receptors affect specific personality traits. Since dopamine is associated with wanting, satisfaction, and attention, the receptors evident in the gene code could adjust personality traits accordingly. While one form of the receptor could make a person novelty seeking and extraverted, a less effective version of the receptor would predispose a person for substance abuse and obesity due to impulsivity (Pinker 2009). Testing has further expanded to serotonin as well by looking at the genes in charge of SERT, the serotonin transporter, and its link to anxiety and depression. There are a variety of genes that match up with the lengths of the SERT in the human body, and the varying lengths are linked to how affectively the SERT work to transport serotonin (Pinker 2009). Pinker explains that knowing the genetic makeup of our personality leads to fear of determinism – that behaviors and traits will be blamed on genetics instead of holding actions and free will accountable. Furthermore, the fear that boiling human behavior down to just the gene code creates a sense of nihilism (Baer et al. 2008; Pinker 2006). Despite this, Pinker states that understanding the science of human nature only furthers our relation to the moral nature of human kind and expands the understanding of human individuality (Pinker 2006).

Pitfalls

Pinker discusses that the costs of personal genome testing are high, ranging from \$400 for 23andMe to \$99,500 for Knome (Pinker 2009). These initial high costs are due to the infancy of the technology,

and as it matures and becomes more popular, Pinker hypothesized that the prices would become much more accessible. The accessibility, however, lends itself to future political issues. George Bush signed the Genetic Information Nondiscrimination Act in 2008 in order to make job or health insurance discrimination due to genetic information illegal and several states are taking action against genetic companies saying they're overstepping by ordering tests only doctors can order (Pinker 2009). As accessibility increases, new abuses of genetic data will likely arise, and more political restrictions to prevent this will follow. Furthermore, there will likely be "paternalistic measures" to prevent genetic testing from gaining momentum, but Pinker believes people's desire to know this information will not allow the industry to remain stifled (Pinker 2009).

Conclusion

According to Steven Pinker, despite the potential financial and ethical drawbacks, genetic determinism offers endless future possibilities of global genetics and provides the opportunity for individuals to personally become active agents in their genetic potential (regarding reproduction and insurance/medication).

Stick Tools for Foraging

Eduardo B. Ottoni
Institute of Psychology, University of São Paulo,
São Paulo, Brazil

Synonyms

[Pounding tools](#); [Probing tools](#)

Definition

Use of sticks as probes or pounding tools to reach or process food items.

Introduction

Tool use is defined as the employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself, when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool (Shumaker et al. 2011). It was once seen as an exclusively and defining human trait, but is, in fact, widespread throughout the animal kingdom, and does not necessarily imply complex

cognition or learning, but can result from stereotyped, species-specific behaviors.

Sticks can be employed as tools by nonhuman animals, from insects to primates, in a variety of contexts, and from play and exploratory behavior to bodily care, as weapons or as props in communicative displays.

The use of sticks in foraging contexts is present in the behavioral repertoire of avian and primate species, but has been, more rarely, observed in other animal taxa, such as crocodilian reptiles (which use sticks as lures to attract avian prey). Sticks can be used to manipulate prey or to dislodge it from nests, tree holes, or rock crevices.

Probe Tool Use in Birds

Woodpecker finches (*Cactospiza pallida*) inhabiting the drier vegetation zones in the coasts of the Galapagos Islands use modified twigs or cactus spines as probes to pry arthropods out of tree holes (in humid areas, where food is more abundant and seasonally more predictable, they rarely use tools; Tebbich et al. 2002).

The most renowned probe-tool-using birds, though, are corvid species, most notably, the New Caledonian crows (*Corvus moneduloides*), from New Zealand. In the wild, they extract beetle larvae from wood using probes with “hooked” ends made (by trimming and sculpting) from sticks or leaf stems or with the aid of “stepped tools” made from the leaves of *Pandanus*, cut in tapering shapes, with the leaves’ barbs used as hooks (Hunt and Gray 2003).

The role of social learning in bird tool use is still unclear. In the case of woodpecker finches, experiments showed that this behavior depends on very specific learning dispositions, involving trial-and-error learning during an early sensitive phase. Though field studies with New Caledonian crows suggest some culturally based local variation, experimental laboratory studies with hand-reared juvenile crows, without discarding individual and cultural transmission, point to a greater role of inherited species-typical action patterns (Kenward et al. 2006).

Probe Use in Nonhuman Primates

Although captive primates may exhibit sophisticated object manipulation (spontaneously or in experimental settings), such as combining sticks to get out-of-reach food (as the chimpanzees in Koehler classic experiment), the spontaneous and *customary* (shown by most or all relevant individuals) or *habitual* (shown by at least several relevant individuals) use of tools by wild primate populations seems restricted to a few species, its discontinuous occurrence apparently reflecting convergent evolution (due to a conjunction of social, cognitive, and ecological conditions), rather than phylogenetic proximity. Nonhuman primates' lithic tools do not typically involve the modification of raw materials; probe tools, on the other hand, are frequently manufactured – sticks being modified by the trimming of side branches and leaves, by peeling the bark, and/or by shaping the points. The customary use of sticks as probing or pounding tools for foraging has been observed in some populations of apes (chimpanzees and orangutans) and New World monkeys (bearded capuchin monkeys).

Probe Tool Use in Bearded Capuchin Monkeys

The use of lithic tools is widespread among savanna populations of tufted capuchin monkeys (*Sapajus* spp.). The customary use of stick probes, though, has so far been only observed in the population of bearded capuchins (*S. libidinosus*) inhabiting the Serra da Capivara National Park, in northeastern Brazil (although there are a couple of anecdotal reports from other sites). These sticks are used to probe for water, or insects in their nests, to poke dangerous animals, or to dislodge small vertebrate prey from rock crevices. Probing tools usually undergo some modification steps (peeling, trimming of side branches and leaves) and may occasionally be used in association with stone tools. For reasons yet unclear, there is a strong gender bias, probe use being an almost exclusively male activity in this population (Falótico and Ottoni 2014).

Probe Tool Use in Orangutans

Wild orangutan populations in a few swamp sites, such as Suaq Balimbing in Sumatra (*Pongo*

abelii) and Gunung Palung in Borneo (*Pongo pygmaeus*), exhibit customary use of stick tools to extract honey from bee nests or (in some Sumatran populations only, absent in Borneo) to open *Neesia* fruits and remove irritating hairy material. Though orangutans are usually very dexterous in captive or semi-free (rehabilitation) conditions, probe tool use is only observed, in the wild, in atypically gregarious and tolerant social contexts, which strongly argues for its socially biased learning and, therefore, its traditional nature: van Schaik and colleagues (2003) believe that neither genetics nor ecology suffice to explain the distribution of tool use in wild orangutans.

Probe and Pounding Stick Tools Use in Chimpanzees

Leaf petioles are used by Bossou chimpanzees in the extraction of oil palm shoots' material by "pestle pounding," and sticks are used to break termite nests and beehives, to access the insects or honey, by many populations.

The use of stick tools in termite and driver ant fishing is customary in many chimpanzee populations in eastern Africa. Termite fishing frequently involves the associative use of two sticks, one to perforate the termite nests' walls (thicker, blunt ended) and another thinner one (with a brush-shaped tip) for fishing the insects. It has been reported in more than 20 populations, including Bossou, Gombe, Fongoli, and Mahale K and B communities (but it is absent in the Mahale M community and is not habitual in Bossou).

Driver ant (*Dorylus* spp.) "dippers" usually employ a "pull-through" technique (gathering the ants from the stick with a hand; Gombe, Bossou) or "direct mouthing" (taking the ant-laden stick directly to the mouth; Taï, Bossou). Carpenter ants (*Camponotus* spp.) "fishing" in trees was first observed in Mahale, then appeared as an innovation in Gombe.

Chimpanzees from Fongoli (Senegal) use sticks as spears to hunt vertebrate prey such as bushbabies (*Galago senegalensis*). Sticks and twigs are also used to probe honeybee nests, to extract water from holes, and the marrow from *Colobus* monkeys' bones.

Conclusion

To examine the potentially cultural nature of behavioral variation between chimpanzee populations, Whiten et al. (1999) compared the repertoires of seven long-term field studies, trying to sort out variation explainable by genetic differences or by particular environmental pressures or affordances (including the availability of the necessary materials). Interpopulation differences in 39 behavioral patterns (including tool use for food acquisition and processing) seemed not due to genetics or ecology and were thus considered as cultural variations. This comparative method can be useful for the detection of potential cultural traits, but, by itself, can be prone to “false positives” (and “false negatives”); therefore, supplementary developmental (and experimental) studies focusing the role of socially biased learning are necessary. One example is the above-mentioned regional variation in use of sticks to gather driver ants. It was initially considered an evidence of cultural variation; subsequent observations suggested that those different techniques could be explained by differences in the behavior of the distinct ant species available in each site. Further investigation pointed to a more complex scenario, involving both environmental causes (ant behavior) and socially learned components (Schöning et al. 2008).

The different approaches by chimpanzees from populations with different toolkits, when facing a probe-related experimental task (Gruber et al. 2009), also suggest a cultural bias in their problem-solving abilities: only the group exhibiting customary probe use solved the task. In a similar study, Serra da Capivara capuchin monkeys readily solved a probe-using task, while monkeys from a non-probe-using population (Fazenda Boa Vista), 350 km away, did not (Cardoso and Ottoni 2016).

Though there is plenty of evidence of social biases in individual learning (usually involving the curiosity of youngsters and the tolerance of adults), reports on the occurrence of some form “teaching” among nonhuman primates are virtually nonexistent. Christophe Boesch reported the observation of a chimpanzee mother from the Tâi

Forest (Ivory Coast) correcting their infants’ handling of wooden hammer tools. In the case of termite fishing, a gender bias in the performance of young chimpanzees suggests an effect of the close observation of their mothers’ behavior (females spend more time with the mothers than males and become proficient probers at younger ages), and a recent study has conveyed evidence of “functional teaching” (or “scaffolding”), with mothers donating probes to their infants (Musgrave et al. 2016).

- [Out-Group Members](#)

Stigmatization and Ostracism

Sarah Beth Bell¹ and Nathan DeWall²

¹Department of Psychology, University of Kentucky, Lexington, KY, USA

²University of Kentucky, Lexington, KY, USA

Definition

Stigmatism refers to any characteristic that causes people to be labeled as undesirable. People often ignore, exclude, or ostracize those who are stigmatized.

Introduction

Humans have a need to belong. Our communities provide us the emotional support we need to thrive. But sometimes an individual or community decides to ostracize someone.

From an evolutionary perspective, it is adaptive to avoid people who seem sickly because

they could spread a harmful disease (Kurzban and Leary 2001). Others can threaten our general well-being, such as free riders (Trivers 1971). Finally, to survive and thrive, it aids an advantaged group to keep resources to themselves – it is often not to their direct benefit to share their goods with a less advantaged outgroup (Sidanius 1993).

Disease-ridden cheaters are not the only people we ostracize. Looks alone can lead to stigmatization and ostracism. Obese people face stigma because many perceive them as lazy (Hebl and Heatherton 1998). Sometimes people automatically judge stigmatized people (Smart Richman and Leary 2009). Racial stereotypes can lead to ostracism because one group seeks to keep a social advantage within their own group (Lareau and Horvat 1999).

Getting left out hurts (Leary and Springer 2001). The pain of ostracism can cause people to act out in ways that are maladaptive. Anger is a common response to social rejection, even though it does not help repair social bonds (Leary et al. 2006). Lashing out at those who ostracize us might be adaptive in our evolutionary past, but vengeful outbursts are maladaptive in modern times (Smart Richman and Leary 2009). Likewise, withdrawing further from the social group may give a person time to nurse wounds, but it hardly repairs the social bond (Vangelisti et al. 2005).

Conclusion

Humans have fundamental motivations to be liked and included. Stigma and ostracism threaten these motivations. Undesirable or dissimilar traits can encourage us to favor our own group members and ostracize others. By understanding stigmatization and ostracism, psychologists can understand how to promote acceptance and inclusion.

Stimulation of Partner's Genitalia and Having Partner Stimulate Genitalia

► Sexual Behavior

Stimulus Generalization and Discrimination

Androulla Ioannou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

Stimulus generalization refers to a set of stimuli sharing similar properties with the original stimulus

that provoked a response. *Stimulus discrimination* is the ability of an organism to respond only to the original stimulus, and not to other similar stimuli.

Introduction

The concepts of stimulus generalization and stimulus discrimination are encountered within the context of associative and non-associative learning.

Differentiation of Stimulus Generalization and Stimulus Discrimination Concepts

Both concepts are inherent mechanisms in the processes of associative and non-associative learning, and for both processes to take place, it is essential that a stimulus model should be stored in memory in order for comparisons with new stimuli to take place.

To begin with, generalization occurs when an organism produces the same response to different stimuli. Stimuli who exhibit analogous properties to the original are more likely to provoke a response: habituation. There could be variations in terms of the level of pitch, brightness, loudness, and so on; however, if these variations deviate significantly from the properties of the original stimulus, generalization will not occur; hence, it is more likely that habituation will not occur either Teyler, Chiaia, DiScenna, Roemer (1984). Stimulus generalization of habituation can only be determined when a second habituation series is done with the use of a novel stimulus. With a comparison of the rates of habituation between the original and the novel stimulus, the amount of generalization will be demonstrated. More rapid habituation in the second series would be indicative of generalization whereas similar rates between the two series would be indicative of a lack of generalization Petrinovich and Widaman (1984).

On the other hand, if stimuli are rather dissimilar than similar, the opposite process of stimulus generalization, the so-called *stimulus discrimination* will be activated. In *stimulus discrimination*, the organism shows the ability to differentiate

between similar stimuli and only to respond to a specific stimulus, hence the organism responds differently to the two stimuli. *Stimulus discrimination* is particularly important in the process of habituation, as it can be used to dismiss sensory adaptation and fatigue as an alternative explanation of the occurrence of habituation. Further, *dishabituation* is indicative of the ability to discriminate, therefore ending habituation Thompson and Spencer (1966). It is important to clarify, however, that dishabituation occurs due to repetitive stimulation of a completely irrelevant stimulus and should not be thought of as the same as stimulus discrimination. Finally, stimulus generalization is useful because it allows for learning to take place quickly in new situations that share similarities with past experiences and promotes the transfer of skills into similar situations thus saving time and effort. Stimulus discrimination offers assistance in a practical level as well.

There are well-known experiments undergone within the concept of conditioning (Pavlov's and Watson's experiments) that illustrate the stimulus generalization and the stimulus discrimination concepts more elaborately.

Conclusion

Stimulus generalization and discrimination are crucial processes in learning and both are of paramount importance to adaptation. Clearly, any organism that lacks such abilities would have minimal chances of survival.

Stone Hammers

Eduardo B. Ottoni

Institute of Psychology, University of São Paulo, São Paulo, Brazil

Synonyms

“Hammer” and “anvil” stones; Percussive lithic tools

Definition

Use of stones as percussive tools.

Introduction

Tool use, per Beck's definition (Shumaker et al. 2011), is the employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or

condition of another object, another organism, or the user itself, when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool.

Once conceived as an exclusively and defining human trait, the use of tools is, in fact, widespread in the animal kingdom, from *Ariadna* spiders, which use tiny quartz pebbles as web enhancements, to the complex and variable toolkits of a few primate species in the wild. Therefore, tool use does not necessarily imply complex cognition or social learning and can result from stereotyped, species-specific behaviors. Though spontaneous tool use in the wild is usually associated with foraging activities, tools may be employed in a variety of contexts, such as exploration, bodily care, play, aggression, or communication.

There is at least one report of “hammer” stones used by an insect: digger wasps (*Ammophila* and *Sphex*) hammer the closure of their egg-filled burrows with small pebbles. Among vertebrates, the use of lithic tools has been observed in bird and mammal species, which may employ them in a variety of ways, from dropping on aggression targets to using them as “hammers,” “hoes,” “blades,” or “projectiles.”

Use of Stone Hammers in Birds

Egyptian vultures (*Neophron percnopterus*) may kill lizards or break ostrich eggs to consume their contents, using stones they raise in their beaks. There are reports of American crows using rocks (held in their talons) to hammer acorns and of a captive bald eagle doing the same to predate crickets and scorpions.

Use of (Passive) Stone “Hammers” in a Non-primate Mammal

Among non-primate mammals, there is at least one, well-known case of percussive stone tool use: sea otters (*Enhydra lutris*) crack mollusk shells by hammering them with their hands against “anvil” stones resting on their chests. This is a very flexible behavior, with great

individual and intergroup variation – much of which seems to be explained by the type of prey consumed. There seems to be also a strong innate predisposition to use tools, since captive sea otters’ pups exhibited this behavior without previous experience. On the other hand, there is evidence of matrilineal transmission of food preferences, which, along with the observation of other skilled individuals, might facilitate the social transmission of this behavioral pattern (Fujii et al. 2015).

Use of Stone Hammers in Nonhuman Primates

The spontaneous and *customary* (shown by most or all relevant individuals) or *habitual* (shown by at least several relevant individuals) use of lithic tools by wild nonhuman primates seems to reflect convergent evolution rather than phylogenetic proximity, being apparently restricted to populations of a few species: chimpanzees, tufted capuchin monkeys, and long-tailed macaques. The known cases of wild nonhuman primates’ stone tool use do not involve *manufacture* (modification of raw materials). *Secondary* tools (tools produced with the use of other tools), though, have been observed, as well as the *associative use* (of more than one tool combined in the same task), in the *tool sets* of stone “hammers” and “anvils” or in the combined use of stone “hammers” and stick probes in a single task.

Tufted Capuchin Monkeys (*Sapajus* sp.)

The use of stones as “hammers” by tufted capuchin monkeys (to crack open palm nuts) was initially studied in semi-free-ranging groups in Brazilian urban parks. Although tool use (lithic or otherwise) seems virtually absent in forest populations, surveys of wild groups in central-western Brazil have shown that, for savannah populations, the use of tools to crack open hard food is rather the rule than the exception, stone “hammers” being associated with stone or wooden “anvils.” The degree of terrestriality – rather than food scarcity – is, apparently, a stronger predictor of the use of stone “hammers” to process defended food in present populations – although

the evolutionary history of tufted capuchin monkeys, occupying savannah environments in times of intense climatic change, suggests a role for hard-shelled fruit as fallback food in the past. The first direct and systematic observations of stone-aided encapsulated food processing in the wild were done with two populations of bearded capuchin monkeys (*Sapajus libidinosus*) in the state of Piauí (northeastern Brazil), in Fazenda Boa Vista, and in Serra da Capivara National Park (Otoni and Izar 2008). In Serra da Capivara, the monkeys exhibit an atypically complex toolkit (including stones and sticks); stone tools are employed not only for cracking nuts but also for digging roots and arthropods' nests and, in one group, as part of females' estrus display (Falótico and Otoni 2016). The broader distribution of stone tool use (as compared to the use of stick probes) among capuchin monkeys' populations may be due to the lasting remains of nut-cracking activity (the "nut-cracking sites"), which enhance the opportunities for delayed socially biased learning, by "local enhancement."

Long-Tailed Macaques (*Macaca Fascicularis*)

Most reports of tool use by Old World monkeys refer to cercopithecines. Small stones are handled in play situations by some populations of Japanese monkeys (*Macaca fuscata*). There are anecdotal reports of the use of stones by macaques and baboons to smash scorpions and about captives using percussive tools in a variety of ways.

The only Old World species where customary use of stone tools has been observed in the wild, though, are long-tailed macaques. The Burmese subspecies (*M. fascicularis aurea*) employ stones to detach or break oysters, gastropods, crabs, and fruit. They transport stones of up to 2 kg and use them as "hammers" to smash open food or as "axes" to extract shellfish from beach rocks – selecting the proper shape according to the usage (Gumert et al. 2009).

Chimpanzees (*Pan Troglodytes*) and Other Apes

Tool-aided problem solving by captive chimpanzees has been extensively observed in a variety of contexts, experimental or not, since Koehler and

Yerkes studies in the 1920s. Orangutans, gorillas, and bonobos, too, frequently exhibit the use of percussive tools in captivity (or rehabilitation) conditions. Kanzi, a symbol-language-proficient bonobo, even produced blades by flaking stones. The customary use of stone tools by apes in the wild, though, seems restricted to chimpanzees.

Wild chimpanzees modify and use as tools a wide range of objects, mostly in foraging, but also in communicative, bodily care, or other contexts. Tool-aided nut cracking had already been reported in the nineteenth century, but the first long-term field studies in the 1960s revealed not only the complexity of their social life but also their technical skills – and a lot of interpopulation variation (McGrew 1992). The customary use of stone or wooden "hammers" for nut cracking is common in West Africa (Guinea, Ivory Coast, Liberia, and Sierra Leone), though techniques and materials vary, but is virtually absent in Central and East Africa – even where nuts and stones are also available. In the Taï forest (and other sites), wooden or stone "hammers" are usually employed to crack *Coula* nuts. For the harder *Panda* nuts, stone "hammers" are the preferred choice. Diécké chimpanzees and other populations crack these nuts with stone hammers and stone or wooden "anvils." In Bossou, where nut-cracking behavior is studied in a "field laboratory," chimpanzees crack softer palm nuts with smaller stone tools. They may employ different techniques to level the "anvil" stones, turning or repositioning them (Matsuzawa et al. 2011).

Conclusion

The study of tool use in wild nonhuman primates has had a central role in the development of "cultural primatology," since interpopulation variation is not usually explained away by genetic differences or environmental constraints and affordances. The "comparative approach" (Whiten et al. 1999) cannot, by itself, establish the "cultural" nature of nonhuman primates' tool use but has paved the way to further longitudinal and experimental studies that examined the role of socially biased learning in the individual

acquisition of local behavioral variants, thus supporting the characterization of tool use repertoires as behavioral traditions.

Furthermore, since the use of lithic tools leaves lasting remains, archeological techniques can be applied in the search of ancient evidence of non-human primates' technology. Archeological evidence has already shown that Tāi chimpanzees have been using stones as “hammers” and “anvils” for nut cracking for at least 4,300 years (Mercader et al. 2007) – and that bearded capuchin monkeys have been using stone “hammers” to process cashew nuts for at least 700 years (Haslam et al. 2016).

Stranger Anxiety

Sujita Kumar Kar¹ and Meha Jain²

¹Department of Psychiatry, King George's Medical University, Lucknow, UP, India

²Department of Pediatrics, All India Institute of Medical Sciences, Patna, Bihar, India

Synonyms

Anxiety of strangers; Fear of strangers

Definition

Anxiety response on encounter with strangers during early infancy and childhood.

Introduction

Human being is a social animal. Human interact with its environment in an intricate manner. The part of the environment that is repeatedly and consistently exposed to the individual becomes familiar over a period of time and the part of the environment that is never to rarely exposed remains unfamiliar to the individual. When it comes to human interaction, classically the unfamiliar persons were recognized as strangers. However, an individual may not interact with all the individuals with whom, he/she is repeatedly exposed; these individuals were called as familiar strangers (Agnel 1999; Paulos and Goodman 2004).

When anxiety is discussed from the developmental perspectives of an individual, anxiety to specific environmental stimuli or environmental change develops during the late part of the first year of life (Scher and Harel 2008). The specific environmental stimuli or environmental changes are exposure to a stranger (stranger anxiety) or being separated from an attachment figure like parents or caregivers (separation anxiety).

Evidences suggest that maternal depression can attribute to the development of stranger

anxiety in the child (Gartstein et al. 2010). The children, who develop anxiety with strangers, are often seen to have internalizing response. They often experience anxiety and guilt, avoid situations, and remain withdrawn to self (Baker et al. 2012). Various factors (temperament of the baby, nature of mother-baby attachment, gender of the stranger, context of exposure with the stranger, as well as availability of any attachment figure) play pivotal role in development of stranger anxiety in an infant (Tsola and Anastassiou-Hadjicharalambous 2011).

Evolution of Stranger Anxiety

The stranger anxiety has been found to have an ontogenic adaptation, i.e., the development of stranger anxiety during the origin of human species. Since ancient times males of different cultures have been found to deliberately kill out-group infants. The out-group male infants were killed to reduce the potential out-group male competitors and female infants were killed to reduce the possible reproductive resource for out-group males and their kin. It has also been observed that during those times more of male infants were killed as compared to the female infants. A tribe of Brazil have been found to kill boys more so as to reduce the warrior population of out-group tribe (Chagnon 1983). It has also been observed that langurs, a primate species, tend to target more of out-group male infants as compared to female infants (Hamai et al. 1992). Thus, the individuals are predisposed to have fear of strangers as this helps in protecting them from the stranger violence that was present in the ancient times.

Anxiety to strangers also has a protective role from the evolutionary perspective. Anxiety is an alarming response to the individual to get aware of the unknown (stranger), who may possess threat. So, stranger anxiety enables an individual to combat threat from stranger. Similarly, during the course of cognitive development, social cognition and abstract reasoning develops late during the childhood; infants and toddlers are deficit in these cognitive functions. Deficits in social cognition and abstract reasoning might result in

development of stranger anxiety. An infant or child with concrete thinking may perceive an unknown individual in more threatening way and due to deficits of social cognition may not be able to anticipate and predict the reality.

This stranger anxiety has been found to reduce as the infant grows because of two reasons: habituation and executive inhibition (Hahn-Holbrook et al. 2010). As children grow, they tend to come in contact with many strangers. Parents help the infant in socializing with strangers. Thus, as the child gets exposed to various strangers, the fear of strangers reduces. Executive inhibition has been found to be inversely related to stranger anxiety. It develops during the 10–12 months when stranger anxiety generally reduces (Diamond 2006).

Implications of Stranger Anxiety

Evidences suggest that early life (infancy) stranger anxiety can be a predictors of development of separation anxiety disorder in children (Lavallee et al. 2011). Stranger anxiety explains a failure in communication process with a stranger. The anxiety responses are often inhibited during effective communications with strangers (Duronto et al. 2005). Stranger anxiety also predicts the avoidance behavior during communication. Extreme degree of fear to stranger also predicts about future risk of development of separation anxiety disorder (Brooker et al. 2013).

Evidences suggest Respiratory Sinus Arrhythmia (RSA) has association with fear and anxiety experience in young children. Successful regulation of anxiety and fear during interaction with stranger results in suppression of RSA (Brooker et al. 2013).

Conclusion

Stranger anxiety is an important mental phenomenon in early age, which has developmental significance. Persistence of stranger anxiety and more severe form of stranger anxiety may be considered as abnormal, which may predict the future risk of development of anxiety disorders.

Strategic Aggression

Pamela Dahlin, Brian K. Dashner and Andres Duarte
Albizu University Miami Campus, Miami, FL, USA

Synonyms

Calculated; Evolutionary aggression; Hostility; Organized; Planned; Proactive aggression; Tactical; Violence

Definition

Strategic aggression is an organized set of tactical and calculated sequences of actions that may increase the probability of enhanced evolutionary fitness and reproductive success.

Introduction

Historically, aggressive tendencies have been a fundamental characteristic among mammals. Strategic aggression specifically is an adaptive trait leading to an increased chance of reproduction and survival of the fittest. In humans, functional strategic aggression was used by hunter gatherer tribes for acquiring resources and improving social standing (Hawley et al. 2013).

Aggressive behavior functions as a set of evolved responses to frequent evolutionary problems such as fending off danger and actively competing for resources (Archer 2001).

Strategic aggression, synonymously known as proactive aggression, is conducive to predatory behavior because it does not show overt signs of threat. The adaptive benefits of strategic aggression are distinguishable from reactive aggression in that reactive aggression is associated with high physiological arousal including verbal (i.e., threats) and non-verbal (i.e., body language/posturing) communication of intent and utilizes immediate ways to protect one's own well-being. By contrast, proactive aggression is characterized by low physiological arousal, a lack of social communication, and targeting of vulnerable body parts. Proactive aggression applies specific strategies in order to obtain valuable resources in a tactical manner (Wrangham 2017).

Sex Differences

From an evolutionary perspective, strategic aggression was demonstrated through both cooperative and competitive means. In this aspect, males experienced more adaptive benefits than females from planned aggressive behavior. Males in nomadic tribes of hominids and early humans had to compete with one another for access to mates and valuable resources that bolstered their likelihood of survival and reproductive success (Klasios 2019). Additionally, it was the physically larger males who were responsible for most of the hunting to acquire meat for the tribe. Hunting was often a cooperative effort, especially when targeting larger animals such as mammoths or buffalo (Sheets-Johnstone 1986). Thus, males with greater ability to successfully plan both kinds of aggressive acts experienced increased fitness and improved their probability of passing on genes rich with strategic aggressive behavior.

The human history of adaptive strategic aggression in males resulted in lasting sex differences that remain today across cultures. For instance, males commit the vast majority of all

homicides (87%) and are also the majority of homicide victims (75%) globally (Duntley and Buss 2011). This suggests a large prevalence of male-on-male violence likely stemming from many of the same evolutionary problems: competition for mating opportunities and favorable resources.

Then and Now

From an evolutionary perspective, the advancement of survival and reproductive success through strategic aggressive means (i.e., hunting and interpersonal skills) became an adaptive quality that promoted evolutionary fitness via ancestral selection pressures. The current implications involving strategic aggression are still influenced by survival of the fittest; however, the emphasis now is placed on more covert acts on aggression rather than directly hurting others. Certain types of violence were adaptive in ancestral conditions that now negatively impact individuals (Klasios 2019). Whereas simply harming a rival could have solved an evolutionary conundrum in previous generations, the consequences of committing a similar act today often result in unfavorable outcomes that decrease fitness. For example, the development of preventative regulations and law enforcement has expanded the evolutionary costs of violent behavior. The present-day consequences of these acts often include incarceration or fines, both of which reduce resources and mating opportunities. While there are still instances today in which acts of direct planned violence may avoid evolutionary costs and serve as adaptive behaviors, covert forms of strategic aggression have also evolved over time with the purpose of avoiding the newer maladaptive costs now associated with violent actions.

Conclusion

In conclusion, strategic aggression represents calculated aggressive tactics individuals use while interacting with others (Archer 2001). These tactics include forcibly acquiring adaptive resources and

involve elements of competition as a way of advancing oneself in an organizational setting. If perceived challenges arise toward a potential rival, hostile strategies may enhance the likelihood of success. While the specific strategies incorporating hostile behavior to obtain a desired goal have changed over time, the evolutionary mechanisms underlying proactive aggression remain intact.

Strategies for Successful Cooperation

Sandra H. Goff
Skidmore College, Saratoga Springs, NY, USA

[Core design principles](#); [Evolution of cooperation](#)

Definition

Strategies for successful cooperation are the mechanisms by which cooperation, the act of

engaging in a behavior which benefits another, is able to evolve and persist.

Introduction

Cooperation, the act of bestowing a benefit upon another, encompasses both mutually beneficial and altruistic behaviors (West et al. 2011, 2007a, b). The evolution of cooperation in a world characterized by competition over scarce resources is generally regarded as puzzling (Ben-Ner and Putterman 2000; Lewis and Dumbrell 2013; Nowak 2006; Rand and Nowak 2013; West et al. 2011), yet cooperative behaviors are frequently observed across human and nonhuman species (Jaeggi et al. 2010; Phillips and Dykhuizen 2015; West et al. 2007a). Cooperation evolved and has been maintained through mechanisms which trigger the behavior under conditions which, on average, foster a positive net benefit. Strategies for successful cooperation should, and do, make best use of evolved mechanisms and predispositions to increase the prevalence of cooperation in modern human societies.

Defining Cooperation

A proper discussion of cooperation requires first a clear definition. Although many authors speak of cooperation as either distinct from or interchangeable with altruism (Barclay 2013; Jaeggi et al. 2010; Phillips and Dykhuizen 2015) or adopt that cooperation is universally costly to the cooperator (Lewis and Dumbrell 2013; Nowak 2006; Rand and Nowak 2013), still others define altruism and mutually beneficial behavior as subsets of cooperation (West et al. 2011, 2007a, b). It is the latter definition that is used herein. Under this definition, a cooperative behavior is simply any act that provides benefit to another. Mutually beneficial cooperation is advantageous to both actor and recipient, while altruistic cooperation aids the recipient at net cost to the cooperator. Cooperation is typically characterized as, at best, neutral for the cooperator because natural selection works on relative, rather than absolute, fitness. Any single

cooperative behavior is generally observed to advantage the recipient in excess of the actor. Yet, despite the implied fitness disadvantage, cooperation is frequently witnessed across human and nonhuman species (Phillips and Dykhuizen 2015; West et al. 2007a). The challenge, then, is to explain why and how natural selection might favor cooperation or individuals might consciously resolve to engage in cooperative behavior.

Adaptive Problems and the Evolution of Cooperation

Like any fitness-relevant trait, cooperation evolved as a solution to adaptive problems, problems which generations of humans had to overcome to reproduce and survive (Cosmides and Tooby 1994). Evolutionary theory asserts that the propensity to exhibit a trait or behavior must only improve fitness *on average*, not at every instance in which it is employed (West et al. 2011). Thus, the simplest, yet not quite satisfying, answer to the riddle of cooperation is that cooperation provided a fitness advantage over noncooperation, on average, in the ancestral environment, given the recurrent problems posed by environmental characteristics.

Humans are widely believed to have evolved in small groups (Ben-Ner and Putterman 2000; Cosmides and Tooby 1994; Gowdy and Krall 2016; Phillips and Dykhuizen 2015; Richerson et al. 2016; West et al. 2007b). Our modern social behaviors are a function of that evolutionary history, regardless of any contrasts between the adaptive problems presented by life within small groups and those presented by the current environment (Cosmides and Tooby 2013; Henrich et al. 2010; Phillips and Dykhuizen 2015). Although it is not possible to precisely identify the adaptive problems encountered by our ancestors, the class of problems can be surmised to be those for which cooperation was a potential solution.

The abovementioned mystery of the evolution of cooperation is only interesting and relevant if the ancestral environment could not support unconditional cooperation. Although it is generally agreed that unconditional cooperation is

likely, if not destined, to fail (Cosmides and Tooby 2013; Nowak 2006), unconditional cooperation could evolve and persist given a particularly harsh environment. The interdependence hypothesis (Tomasello et al. 2012) puts forth that collaboration was necessary for survival in harsh ancestral environments. Agent-based models of cooperation have confirmed that interdependence, modeled as a large cost of not finding a cooperative partner, can allow for the evolution and persistence of cooperation (Smaldino et al. 2013). Interdependence is also modeled in games such as the “stag hunt,” an evolutionary game of coordination (Lewis and Dumbrell 2013), in which players can either hunt alone or together. In a particularly harsh environment, payoffs in this game would make hunting alone a poor choice.

The mechanisms that encourage cooperative behavior at present may well be different from those mechanisms which allowed for cooperation to evolve within the ancestral environment (Burkart et al. 2014). More often than not, and especially in modern society, the fitness advantage provided by cooperation is vulnerable to noncooperative strategies capable of taking a “free ride” on the cooperation of others. Given these vulnerabilities, the characteristics of our human ancestors, and the adaptive problems posed by their environment, particular mechanisms were differentially successful at maintaining cooperative behavior (Jaeggi et al. 2010; West et al. 2011) because they signaled the need to use cooperation judiciously.

The formulation of strategies for successful cooperation in modern society is aided by addressing two questions: (i) in the absence of an environment capable of producing sufficient interdependence such that unconditional cooperation is the norm, what are the solutions or mechanisms that have developed to allow cooperative behavior to persist despite the existence of noncooperative strategies in the population? and (ii) how can this knowledge be used to manipulate a situation for the purpose of increasing the probability of cooperation? This paper provides a brief overview of answers to both questions. First, proximate mechanisms widely acknowledged to support the evolution of cooperation are reviewed.

Next, connections between these mechanisms and Elinor Ostrom's core design principles (Ostrom 1990; Wilson et al. 2013) are explored. The paper concludes with suggestions for creating successful strategies for cooperation which build upon both the proximate mechanisms for the evolution of unconditional and conditional cooperation and Ostrom's work.

Proximate Mechanisms for the Evolution of Cooperation

The decision to cooperate, to benefit a recipient, sometimes at cost to oneself, can be deliberative or automatic. Although deliberative acts likely involve a conscious weighing of benefits and costs, automatic or instinctive, cooperation does not require conscious decision-making (Bear and Rand 2016; Lotito et al. 2013). Rather, the propensity to produce a cooperative behavior is at least partially the result of benefit-cost analyses performed by natural selection on an evolutionary time scale. Just as in any benefit-cost analysis there is not likely to be one single cost or benefit that drives the direction of the net benefit of a proposal, there is no reason to believe that there is one particular mechanism solely responsible for the evolution of cooperation. The following discusses a number of popular mechanisms cited as contributing to the evolution and maintenance of cooperation, starting with an explanation of each of the "five rules" (Nowak 2006).

The Five Rules

Five mechanisms are widely acknowledged to allow natural selection to produce cooperation in environments in which both cooperation and non-cooperation exist as strategies: direct reciprocity, indirect reciprocity, spatial selection, multilevel selection, and kin selection (Nowak 2006, 2012; Rand and Nowak 2013). Although Nowak and his colleagues are credited with the synthesis of these mechanisms, each mechanism is widely studied by numerous other researchers. Of note is that some scholars see little difference in the underlying structure of these mechanisms (Fletcher and Zwick 2006; Nee 1989; West et al. 2007a). The unifying rationale for the success of each of the five mechanisms is that the expected benefits of

the act outweigh the costs whenever there is a high probability of being a recipient of a similar benefit in the future, whether directly from the initial recipient or through network or group channels.

Kin selection as formalized by Hamilton (1964) states that cooperation can evolve through natural selection given that the relatedness between the actor and the recipient is greater than the cost-to-benefit ratio, where the cost is borne by the actor and the benefit is received by the recipient. Also referred to as inclusive fitness, kin selection is useful in explaining cooperative behavior amongst genetic (or cultural) relatives, assuming that kin discrimination is possible.

But, an adequate theory of cooperation must also explain the high degree to which humans cooperate with non-kin. Direct reciprocity, or reciprocal altruism (a name notably inconsistent with the definition of altruism expressed here), encourages the evolution of cooperation between non-kin in that individuals are more likely to cooperate with those who have cooperated with them in the past (Axelrod and Hamilton 1981; Nowak 2006, 2012; Trivers 1971; West et al. 2011, 2007a). Specifically, direct reciprocity can evolve when the cost-benefit ratio of the act is less than the probability of future interaction between the two individuals (Nowak 2006). Direct reciprocity is consistent with evidence that individuals demonstrate neural activity associated with reinforcement learning when tracking the past behavior of partners in an economic game (Stallen and Sanfey 2013). It has also been suggested that uncertainty as to the probability of encountering a partner in the future can allow direct reciprocity to produce cooperative behavior in one-shot games. This effect occurs due to the potential to incur the high costs associated with prior noncooperation should interaction between the parties unexpectedly occur in the future (Delton et al. 2011).

Indirect reciprocity expresses cooperation as a function of a process in which individuals help those who have a reputation for being cooperative (Nowak 2006). That social behavior is influenced by the presence of an audience (Jaeggi et al. 2010) provides support for indirect reciprocity as a mechanism for encouraging cooperation. In both

direct and indirect reciprocity, cooperation can evolve and persist because it is conditional upon the likelihood of receipt of future payoffs.

Likewise, spatial selection and network reciprocity can produce cooperation because structured populations have the potential to shield individuals who frequently express a cooperative trait from those who frequently engage in noncooperative behaviors (Nowak 2006; Rand and Nowak 2013). Spatial selection modeled on dynamic networks is similar to indirect and direct reciprocity in that the individual can decide to break the links it shares with noncooperators (Rand and Nowak 2013).

In cultural group selection, an oft-cited source of human pro-social behavior (Boyd and Richerson 2009; Boyd et al. 2011; Richerson et al. 2016; Waring et al. 2017), differences in the cultural characteristics and practices of human groups can be exploited by an evolutionary process much in the same way that natural selection acts upon genetic variation. Group selection requires a high degree of variation between groups relative to the variation within groups and sufficient competition or conflict between groups. The adaptive problems that allow for cooperation through group selection are likely to have been those in which groups consisting of a large proportion of cooperators were able to produce an effective solution or otherwise out-compete groups of noncooperators. The debate about the magnitude of the role of cultural group selection in the evolution of cooperation is well documented in Richerson et al. (2016). Like the four previously described mechanisms, group selection allows the benefits of cooperation to fall disproportionately on the cooperators, if not immediately, at least in the long run.

Additional Potential Mechanisms for the Evolution of Cooperation

Natural selection works on relative differences in reproduction and survival; thus, many researchers have focused on aspects of the ancestral environment which are directly relevant to reproductive success and procurement of sustenance and protection. Cooperative breeding (Burkart et al. 2014) and the signaling of potential parental

investment (Phillips and Dykhuizen 2015) have been hypothesized as potential origins of cooperation. Variance of resource procurement as a function of luck has also been cited as a potential source of cooperation (Cosmides and Tooby 1994).

Burkart et al. assert that allomaternal care is the best predictor of proactive prosociality in human and nonhuman primates, a finding that suggests that the ancestral environment presented problems for which care for offspring provided by non-mothers was a preferred solution. Agent-based simulations demonstrate that the presence of cooperative breeding can be explained at least in part by environmental harshness (Smaldino et al. 2013).

Allomaternal care can also be explained by theories of costly signaling. One hypothesis is that altruistic behavior displayed by males served as a costly, and thereby honest, signal of likelihood to care for offspring (Phillips and Dykhuizen 2015). Here, the costliness of altruistic behavior, a behavior which benefits the recipient at a cost to the cooperator, is essential to the evolution of cooperation, rather than a dilemma that must be solved. However, that the cooperative behavior has potentially significant benefits calls into question its categorization as altruistic as opposed to mutually beneficial.

Many of the principles of sexual selection can be applied to partner choice more generally (Barclay 2013). Cooperative behavior may be used as a costly signal to attract partners in other contexts such as in the choosing of allies or hunting partners. Individuals who witness or receive information about the cooperative behavior of a potential partner may be more inclined to initiate an interaction. The possibility for partner choice is also a necessary precondition for direct and indirect reciprocity.

An additional factor which may have affected the relative net benefits of cooperation was the development of extrasomatic weaponry, weapons that are external to the human form (Phillips and Dykhuizen 2015; Phillips et al. 2014). Prior to the advent of extrasomatic weapons, individuals could use signals of their strength and superiority to avoid potentially costly conflict in which even

the winner was likely to be injured. The development of weaponry, however, allowed individuals the ability to cause harm to another at little to no cost to themselves. Under these conditions, there is selection for the display of cooperative traits that might allow individuals to avoid conflict.

Core Design Principles

Humans can explicitly learn from the mechanisms which allowed natural selection to produce cooperation to consciously develop institutions, policies, and practices that foster cooperation. At the same time, humans are also predisposed to cooperate in specific contexts and make choices with machinery forged by natural selection (Hodgson and Knudsen 2010, p. 50). For these reasons, it is not surprising to find a marked relationship between the previously discussed evolved mechanisms which can produce cooperation and the core design principles as developed and refined by Elinor Ostrom and colleagues (Ostrom 1990; Wilson et al. 2013). The core design principles, a set of eight guidelines for creating successful common pool resource management groups, are readily generalizable to both dyads and collectives.

The core design principles were developed through empirical research that involved the creation of a database of common pool resource organizations from around the world. Ostrom studied the characteristics of those groups which were able to overcome the “tragedy of the commons” (Hardin 1968) and distilled her findings to produce the eight principles briefly described below (Wilson et al. 2013). First, the groups employed clearly defined boundaries. This applied both to the members of the group (it was clear who was a part of the organization and who was not) as well as the resource. Second, groups used the benefits principle, creating proportionality between benefits enjoyed and costs incurred by members. Third, successful groups allowed members to develop group rules and to make decision by consensus. Fourth, members were involved in low-cost monitoring of the behaviors of other group members. Fifth, punishment was used, but was graduated in its severity. Sixth, conflicts

between members were dealt with quickly and fairly. Seventh, groups were seen as having decision-making authority. And finally, nested hierarchies, or polycentric governance, were used when the systems to be managed were large in scale or scope.

Each of these principles connects in some way to mechanisms which allow for the evolution of cooperation. For example, well-defined boundaries, proportionality, group rule development, monitoring, and sanctions help to focus the benefits of cooperation on group members and to ensure individuals that conditions are favorable for the expression of the cooperation trait, i.e., that free riding will not be rewarded. Application of these principles to improve cooperation in other domains is underway (Wilson et al. 2013) but deserves additional attention.

Conclusion

Knowing what signals commonly trigger both cooperation and non-cooperation can assist in designing policy to better achieve desired societal aims. (Stallen and Sanfey 2013, pp. 301–302)

Cooperation can evolve when either environmental conditions are suitable to permit unconditional cooperation or when, in the absence of such an environment, mechanisms exist that cue conditional cooperation. The core design principles provide a comprehensive framework for successful collective action in the latter situation. They implement widely researched mechanisms for the evolution of cooperation in the context of common pool resource management, providing strong empirical evidence for the effectiveness of the mechanisms in the real world.

Strategies that can alter the environment to make it more amenable to unconditional cooperation are more complicated, but worth pursuing. Two potential pathways are through emphasis on interconnectedness and appreciation of the large role that luck plays in life circumstances. Effective and precise methods for invoking these two concepts should be the focus of future research in cooperation.

San Antonio, TX, USA

Synonyms

[Aggression](#); [Antisocial behavior](#); [Physique](#)

Definition

Physical strength has a positive association with levels of aggression.

Introduction

Physical strength has always been a desirable characteristic among humans, particularly males. It has long been suspected that males developed greater physical strength in order to compete in direct confrontations for mates. As such, male's upper body strength tends to exceed that of females (Isen et al. 2015; Darwin 1871; Sell et al. 2012). These traits of physical strength are meant to intimidate rivals. However, physical strength is not as useful for males if they do not also possess psychological and behavioral adaptations that encourage engagement in conflict. Thus, a male that is not only physically strong but also has the psychological need for battle will be the most fit (Isen et al. 2015). Accordingly, it is logical for a relationship to exist between physical strength and aggression.

The Link Between Physical Strength and Aggression

There is evidence in the field of evolutionary psychology, as well as related fields, that there is a positive association between physical strength and aggression. For example, Gallup and colleagues (2007) found that handgrip strength among males predicted past aggressive behavior, with males that have more handgrip strength having higher levels of past aggressive behavior. They also found that the males who had stronger handgrips were more likely to have broad shoulders (Gallup et al. 2007). Similarly, stronger men tend to report more successful resolving of conflicts in their favor than weaker men. They are also more likely to get angered easily and more frequently (Sell et al. 2009).

Research also suggests that particular body types are overrepresented in prisoners and delinquents. William Sheldon (1949) studied males between the ages of 15 and 21 to determine whether a link existed between physique, temperament, and delinquency. He found that there were three predominant body types: endomorphs (soft and round build), mesomorphs (muscular and athletic build), and ectomorphs (skinny and fragile build). Within his sample, the mesomorphic body type was the most likely to engage in delinquency (Sheldon 1949). Sheldon's findings were supported by (Glueck and Glueck 1956), who conducted a study comparing male delinquents to nondelinquents. They found that the delinquent group tended to have wider chests, bigger forearms and upper arms, and larger and broader waists than nondelinquents. Additionally, only 31% of the nondelinquents were found to have a mesomorphic build, while 60% of the delinquent group had a mesomorphic build (Glueck and Glueck 1956).

What Explains the Relationship Between Strength and Aggression?

Since the link between physical strength and aggression appears well established, it is important to determine what causes this relationship. There are currently several explanations for this

association that take somewhat opposing viewpoints. The first explanation, the facultative-calibration view, asserts that physical characteristics of strength precede aggressive behaviors. Accordingly, stronger men receive positive reinforcement when engaging in physical activities, which reinforces the use of aggressive behavior. Thus, strong men have a desire to participate in physical challenges because they have the ability to compete well (Lukaszewski and Roney 2011; Isen et al. 2015). Several predictions from this hypothesis have been tested empirically with results being quite supportive (Sell et al. 2009).

A secondary explanation takes a contrasting position by stating that more aggressive individuals choose to take greater stock in developing physical strength. This hypothesis posits that males who are more aggressive often attempt to increase their physical strength through various forms of exercise (Isen et al. 2015). Support for this explanation can be found in the large body of literature which suggests that aggression is a very stable trait throughout the life of an individual (Huesmann et al. 1984). This line of research asserts that an aggressive child will grow into an aggressive adult, regardless of his physique as a child. A recent study tested this theory by examining boys at age 11 and following them until the age of 17. This study found that antisocial behaviors, such as fighting, tend to precede the appearance of physical strength characteristics. In fact, boys with increased antisocial behaviors in childhood had larger gains in physical strength between the ages of 11 and 17 than boys who did not display antisocial behaviors in childhood (Isen et al. 2015).

The third explanation, the neuroandrogenic hypothesis, is a middle ground between the above two explanations. This framework argues that there is no causal relationship between strength and aggression. Instead they both co-occur because of common biological factors that masculinize the body's physical structure and the brain, independently. Research has found that testosterone exposure affects both physical development and brain functioning, which supports the idea that aggression and physical strength develop independently but around the same time (Ellis et al. 2008).

Conclusion

The physical ability to defeat one's rivals has always been an important trait for males to have. Since physical strength would be relatively meaningless without the internal desire to use that physical ability, it is logical that there evolved to be a relationship between strength and aggression. The positive association between a male's physical strength and their levels of aggression is well established; however, the causal mechanism behind this relationship is not yet known. It is plausible that males with strong physiques are socialized into aggressive behaviors because of their appearance. On the other hand, aggressive males may greatly emphasize increasing their physical strength. There may also be no causal relationship between strength and aggression, but rather both are caused by biological factors.

[Stress reactivity](#); [Stress response](#); [Stressor](#)

Definition

Stress generally describes the process by which an organism perceives and responds to events – often called stressors – that are judged to be harmful, threatening, or challenging. Stressors describe demanding events or situations that trigger coping adjustments in an organism.

Introduction

Through a variety of mechanisms, the stress response regulates a wide range of physiological and behavioral processes that include bodily growth, metabolism, reproductive functioning, attention and memory, learning, aggression,

risk-taking, caregiving, among others (for review, see Del Giudice et al. 2013). For example, neurobiological mechanisms underlying the stress response include hierarchical, coordinated action of the autonomic nervous system and the hypothalamic–pituitary–adrenal axis (HPA), as well as feedback loops with cortical brain structures. Natural selection has shaped the stress response to increase the ability of organisms to cope with environmental stressors, with stress-related response mechanisms emerging early in the history of life.

Functions of the Stress Response

The stress system is a highly complex, sophisticated, and carefully regulated adaptation that has been shaped by natural selection because it gives a selective advantage. The stress response serves several vital functions and the advantages associated with those functions must be substantial in order to outweigh the significant costs. The first essential function of the stress response includes coordinating an organism's physiological and behavioral response to threats and opportunities in the environment. This includes events that have fitness-relevant consequences for the organism, requiring the organism to make adjustments in an effort to respond effectively. Environmental opportunities may reflect novel or unexpected events, as well as situations that are pleasurable (e.g., signs of sexual availability in a potential mate; see Del Giudice et al. 2013). Challenges in the environment that require adjusting in the whole organism are often referred to as allostasis (McEwen 1998; McEwen and Wingfield 2003; Sterling and Eyer 1988). The stress response mediates this process by coordinating brain-body changes in response to environmental stressors that may be either acute or chronic.

A second function of the stress response includes the encoding and filtering of environmental information. Information about the external environment is received through limbic structures, and interaction with other neuroendocrine systems (e.g., the HPG axis and the immune

system; see Herman et al. 2003) yields complex information that can be utilized by the organism. When the stress response and associated neurobiological systems are activated, useful information is provided related to the probability, type, and severity of threats and opportunities in the environment. This information may be encoded as part of the stress response and can provide a useful type of “summary” of key dimensions of the environment, such as extrinsic morbidity–mortality and unpredictability (Del Giudice et al. 2013).

A third critical function of the stress response extends beyond responding to immediate environmental challenges, and rather, involves the regulation of several traits and behaviors that are relevant to life history (for review of Life History Theory, see Ellis et al. 2009; Hill 1993). For example, baseline activity and responsiveness of the stress response is associated with individual differences in several life history-relevant domains such as competitive risk-taking, learning, self-regulation, attachment, affiliation, reproductive functioning, and caregiving (for review, see Del Giudice et al. 2011).

Phylogeny of the Stress Response

Comparisons across species can provide insight concerning the phylogeny of the stress response. All vertebrate species possess the molecule proopiomelanocortin (POMC), which serves as a precursor to both adrenocorticotrophic hormone (ACTH) and opiate-like peptides – molecules with related functions. Human ACTH shares similar peptide sequences to mammals, amphibians, reptiles, and insects, among others. ACTH is also closely associated with various signaling molecules such as corticotropin releasing hormone (CRH), biogenic amines, steroids, cytokines, and nitric oxide. The genetic sequences for these molecules have been conserved over hundreds of millions of years and serve closely related functions, particularly those involving defense. The small degree of change that has taken place in such molecules over time suggests that they provide many essential functions, creating a strong selective force against

mutations that would otherwise result in a sequence change (Nesse et al. 2010).

As with any trait, the stress response is associated with cost-benefit trade-offs. The trade-off between the long-term costs and the immediate benefits of a relatively quick, intense, or prolonged stress response, ultimately shape the mechanisms that regulate the responsiveness of the stress system. Cost-benefit trade-offs are associated with an organism's resiliency to the effects of stress on physiology or behavior, with neuroendocrine habituation to repeated stressors, and even maternal care (for discussion, see Nesse et al. 2010). Despite the significant costs associated with the stress response, natural selection has shaped this trait because it confers a selective advantage that is greater.

Sex Differences

It is probable that sex differences in biological and behavioral responses to stress arose during human evolutionary history. In the context of life history trade-offs, the associated costs and benefits for males and females are not equal, and thus, life history strategies show consistent sex differences. On average, faster strategies are associated with males who invest more in mating effort – in contrast to parenting effort – than women. The extent to which sex differences in life history-related behavior are expressed, however, depends in part on conditions of the local environment. At the slow end of the life history continuum, males and females engage in high parental investment, and the interests of both sexes focus on long-term, committed pair bonds; in this context, sex differences in behavior are thus expected to be relatively small. However, as life history strategies become faster, sexual competition is enhanced, and sex differences in competitive strategies are expected to be more apparent. Males are also expected to be overrepresented as high-risk, low-investment strategists due to the greater potential benefits of extreme mating-oriented behavior (for review, see Del Giudice et al. 2011, 2013).

It has also been argued (Taylor et al. 2000) that while the nervous system response associated with stress is virtually identical for men and women, there are sex differences in the neuroendocrine and behavioral response to stress that arose over the course of human evolution. It has been proposed that the stress response in women is best characterized as “tend-and-befriend,” where tending involves nurturing activities that are designed to protect the self and offspring, promote safety, and reduce distress. Befriending involves the creation and maintenance of social networks that may contribute to this process. The biobehavioral mechanism underlying the tend-and-befriend pattern is thought to draw on the attachment-caregiving system, with neuroendocrine evidence strongly implicating the hormone oxytocin in conjunction with female reproductive hormones and endogenous opioid peptide mechanisms. Alternatively, the stress response of men is thought to be more typical of the classic “fight-or-flight” pattern, where behavioral responses to environmental stressors involve either fighting or fleeing.

Conclusion

The stress response involves the process through which an organism perceives and responds to events that are harmful, threatening, or challenging as part of an adaptive coping effort. The stress response involves hierarchical, coordinated action between several neurobiological systems. Elements of the stress response are conserved across vertebrates, suggesting that the molecules supporting this response served many important functions. As with any trait, the stress response is associated with cost-benefit trade-offs. The stress response serves multiple critical functions: shaping of the allostatic response, the encoding and filtering of environmental information, and the regulation of several life history-relevant traits and behaviors. Finally, it is likely that sex differences in biological and behavioral responses to stress arose during human evolutionary history.

Stress and Cortisol

Lauren Vorbach¹ and Kevin Bennett²

¹Pennsylvania State University, Coraopolis, PA, USA

²Department of Psychology, Pennsylvania State University, Beaver, Monaca, PA, USA

Definition and Synonyms

Stress, initially described as a physical force, claimed its new meaning as a psychological, physiological, or chemical impact on an individual that changes the body's homeostasis (Chrousos 2009). Examples of stress include strife in the workplace, toxic chemical exposures (e.g., asbestos), and traumatic experiences, such as a house fire. When an individual undergoes stress, the body has its own mechanisms in store to adapt. Chrousos described the adaptation: “When any stressor exceeds a certain severity or temporal threshold, the adaptive homeostatic systems of the organism activate compensatory responses that functionally correspond to the stressor” (2009, p. 374). Researches have yet to explore all the effects of stress on the body; however, they have found a link between stress and cortisol. Cortisol is a hormone secreted by two, golf ball sized glands sitting above the kidneys, the adrenals. Cortisol not only resides within the adrenal glands but also travels throughout the body within the bloodstream (Staufenbiel et al. 2013). Individuals may not detect the effect that cortisol has on everyday bodily function. Researchers have found that stress can alter the way that cortisol is released, used, and stored.

Introduction

Stress is often discussed as a mental tension caused by environmental pressure on the brain and the body. One key factor in the body's response to stress is a hormone called cortisol.

Not only does cortisol aid in adapting the body at that exact moment, but it has longer effects. Cortisol affects other bodily systems and parts, all of which reveal stress as a substantial factor in daily function.

Physiology of Cortisol in the Body

A set of adrenal glands produce the glucocorticoid hormone, cortisol (McEwen 2008). Before the adrenals produce and release cortisol, several things must occur. First, an outside stressor is sensed by an individual. After sensory neurons receive the stimuli and it exceeds the stressor threshold, the impulse is sent to the hypothalamus, a region of the brain dedicated to the autonomic nervous system and homeostatic bodily systems. The hypothalamus releases corticotrophin to the pituitary gland, a pea-sized gland in the brain. The pituitary then produces adrenocorticotrophic hormone (ACTH) and releases it into the bloodstream down to the adrenal glands. The glands release epinephrine and catecholamine, creating the “adrenaline” response individuals may get when presented with a stressor. The adrenals also release norepinephrine, which stimulates the liver (Lee et al. 2015). The hypothalamus, pituitary, adrenal process is often called the “HPA axis” or “HPA loop” (Gómez-Gallego and Gómez-García 2018).

Effects of Cortisol

Researchers found that there are many effects on cortisol of the body. Because the HPA axis involves neurological mechanisms that are responsible for homeostasis throughout the body, cortisol plays a major role in our body’s maintenance. Generally, cortisol can increase sugar within the bloodstream and increase the accessibility of repairing materials throughout the body. Cortisol can also affect an individual’s immunity, digestive system, and reproductive system, depending on levels and cortisol use (Chrousos 2009).

In stressful, flight or fight situations, through the HPA axis, cortisol and adrenaline levels will

rise, and naturally and typically, fall back down to a baseline state through feedback from the hypothalamus and the hippocampus. Researchers have found that when stressors are prolonged, cortisol levels rise; however, it may not come back down to that baseline. Cortisol may stay in the bloodstream and circulate in the body, even after the stressors have been removed. Researchers saw that this acute state can contribute/cause anxiety, depression, heart disease, gastrointestinal diseases/problems, metabolism problems/weight gain, other endocrine/reproductive difficulties, and circadian rhythm (Fogelman and Canli 2018).

Chrousos (2009) listed the effects of both effects of hypo and hypercortisolism and change in the HPA axis. Increased activity conditions include: depression, anorexia, obsessive-compulsive disorder, panic disorder, excessive exercise, alcoholism, diabetes mellitus, obesity, and hyperthyroidism. Decreased activity include: adrenal insufficiency, depression, fatigue, fibromyalgia, premenstrual tension syndrome, hypothyroidism, rheumatoid arthritis, asthma, and eczema.

There are two more well-known diseases related to cortisol levels: Cushing’s syndrome and Addison’s disease. One of them, due to hypercortisolism is called Cushing’s syndrome. Symptoms of Cushing’s syndrome include: weight gain, round face, thin arms and legs, and easy bruising. Individuals may also experience difficulties with reproductive systems, such as irregular menstruation or amenorrhea (Krieger 1983). The other, Addison’s disease, is due to hypocortisolism (i.e., sparse cortisol). Symptoms of Addison’s disease include: fatigue, weight loss, hyperpigmentation, low blood pressure, abdominal pain, and salt craving (Levine et al. 2007).

Diagnostic Measures of Cortisol

Researchers and physicians may test cortisol various ways; however, each way measures cortisol in different areas. Cortisol may be found bound, unbound (free), or both unbound and bound (total). Bound cortisol is attached to “sex-hormone-binding” globin. Unbound cortisol is also found in the blood stream, not connected to

anything. Total cortisol is the combination of bound and unbound cortisol (Levine et al. 2007). Based on what the researcher or physician is looking for, an individual may use hair or saliva samples, urine testing, or blood samples to check cortisol levels (Levine et al. 2007).

In order to begin a blood test, a health professional will take two separate blood samples, one in the morning and in the evening to record change in cortisol levels at different parts of the day. Blood would then be sent to a lab to analyze. Blood cortisol testing can test total cortisol levels (Levine et al. 2007).

The last three samples are less invasive. Salivary and urine samples can also test unbound cortisol (Hellhammer et al. 2009). Both samples can be taken throughout the day depending on the researcher and/or physician's instructions. The last form of testing is taking a hair sample. Because hair is made from capillaries from the skin, blood from the hair can be examined over time. The samples can be taken and sent to a lab for testing (Lee et al. 2015).

Treatment of Stress and Cortisol

Physicians and professionals recommend a variety of treatment approaches to reduce stress and aid in lowering hypercortisolism. Typically, yoga, meditation, and enjoyable activities are recommended. Sullivan, Carberry, Evans, Hall, & Nepocatych described in a recent study, how individuals who participated in a type of restorative yoga had decreased cortisol directly after the class (Sullivan et al. 2017).

Treatment varies for everyone. Some may eventually partake in counseling or therapy. Others may need to lower their stress input to get the body back to homeostasis. Those individuals may need to identify whatever stressor is present and eliminate it or learn how to adapt or change it so that stress is lowered. Sometimes a stressor is physiologically inherent, meaning it is already present in the body. Stress within the body can increase cortisol levels. Seeing a physician about concerns of heightened cortisol levels may be suggested for this individual.

Conclusion

Stress not only changes the way the body functions, but also has long-lasting effects on the body's systems. Managing stress as well as attending the body's response to stressors could aid in cortisol regulation. Awareness of diagnostic methods also increases awareness as well.

Definition

The physiological response involved when faced with a stressor (e.g., interpersonal conflicts, psychosocial, threats), which are based on individual differences.

Introduction

Life History (LH) Theory is a mid-level evolutionary framework used to explain phenotypic variation (e.g., sexual maturation, impulsivity, offspring number) based on developmental exposure to environmental cues (e.g., risks of morbidity and mortality) (Charnov 1993; Stearns 1992). Essentially, exposure to early life adversity leads to systematic differences in response to negative events, which are adaptive for varying environments. From this standpoint, individuals in less affluent areas theoretically adopt “fast” LH

strategies (as opposed to “slow” LH strategies) and are prone to engaging in risky behaviors, employing short-term mating tactics, bearing more offspring, and having higher incidences of mental illness (Charnov 1993; Hurst and Kavanagh 2016; Promislow and Harvey 1990). Reasons for expending resources sooner are due to a lowered survivability and thus an inability to pass down genes to the next generation.

These context-dependent trade-offs are regulated by a sequence of hormonal (i.e., cortisol) and immunological cascades that ultimately influence gene expression (Boyce and Ellis 2005; Shalev and Belsky 2016). Due to the highly conserved pathways involving neuroendocrine mechanisms, it is therefore important to outline the basic biological pathways involved to gain a better understanding regarding the function of stress reactivity and how the body has adapted mechanisms to prepare individuals to respond to threatening or challenging situations (Boyce and Ellis 2005). Additionally, a heightened state of arousal is necessary for unfavorable conditions and will be thoroughly explained as it relates to mortality and longevity.

Hypothalamic-Pituitary-Adrenal (HPA) Axis

The hypothalamic-pituitary-adrenal (HPA) axis plays a crucial role in stress reactivity and regulates other processes such as the immune system, mood, sexual drive, metabolism, and energy. Once activated by a stressor (an agent that causes stress to an organism), the HPA axis then triggers a biological cascade, one that works in conjunction with the central nervous system and the endocrine system. In its basic form, the hypothalamus will release corticotropin-releasing hormone (CRH), then stimulating the release of adrenocorticotrophic hormone (ACTH) located on the anterior lobe of the pituitary gland, which will then secrete glucocorticoids (specifically cortisol, the stress hormone) found in the adrenal cortex. Cortisol will eventually inhibit the activation of the hypothalamus and the pituitary gland once the stressor has passed, functioning as a negative

feedback loop. Cortisol's main role is to regulate energy homeostasis and activate physiological arousal states in response to stress-induced situations. Dysregulation within the system (e.g., chronic stressors) leads to problems surrounding immune functioning (i.e., hyperactivity and immunosuppression), which has been termed as allostatic load (Ellis and Del Giudice 2014). Over time, allostatic load can have detrimental consequences to individuals' health, accelerating morbidity and mortality.

Adaptive Calibration Model

A growing interest within the field has sought to examine the adaptive functionality of immunology as it relates to human ecology. Researchers have argued that prolonged exposure to stressful environments incur physiological harm that is said to be maladaptive, giving rise to disease and other downstream health consequences (see Miller et al. 2011). To this end, the allostatic load model has been the most widely accepted approach to understanding stress reactivity. It has been integral in explaining the pathological effects with regard to dysregulation in the autonomic, neuroendocrine, metabolic, and immune system (Ellis and Del Giudice 2014). Recent theoretical approaches, however, have proposed an alternative viewpoint that aims to conceptualize why these mechanisms have remained throughout human evolution. This approach is called the adaptive calibration model, which is rooted in LH Theory (Ellis and Del Giudice 2014).

The adaptive calibration model is, in essence, an extension and revision to the allostatic load model with a focus on the functionality and a positive take of the stress response system. From an evolutionary perspective, it can provide why phenotypic variation in stress reactivity exists, all of which has been shaped by natural selection (Ellis and Del Giudice 2014). It stands to reason that certain traits were selected for those with chronic exposure to adverse environments. For example, this model has the flexibility to explain why some individuals are able to respond to stressors more quickly than others. Additionally, this model was

heavily influenced by Belsky et al. (1991) who first highlighted the importance of early life adversity, indexed by parental conflict, which served as a proxy for morbidity and mortality.

Psychosocial Acceleration Theory

In their seminal study, Belsky et al. (1991) advanced the field by incorporating a psychosocial element with LH Theory. They began addressing the development of LH strategies (e.g., attachment styles, precarious behaviors, sexual maturation, parental investment), all of which were impacted by harsh early childhood conditions. Their important contribution documented the consequences of father absence and its relationship to reproductive timing, which they described as the psychosocial acceleration theory. The work by Belsky et al. (1991) paved the way for future developmental research using LH Theory as its theoretical framework. Since then, studies focusing on reproductive timing in females have illustrated early childhood adversity to be related to earlier onset of menarche in females, with these individuals adopting behaviors consistent with fast LH strategies (Chisholm et al. 2005; Ellis 2004). Others within the field of developmental psychopathology have also found converging evidence that demonstrates an association between early childhood poverty, maltreatment, and attachment styles later predicting heightened cortisol levels (see Fearon et al. 2016). Recent emergence of evolutionary LH models, however, has suggested that there are two intersecting ecology dimensions: harshness and unpredictability.

Harshness and Unpredictability Dimensions

Harshness is defined as age-related risks for death and disease, whereas unpredictability is defined as the variability at which harshness occurs (Ellis et al. 2009). To test this model, Simpson et al. (2012) sought to evaluate whether early childhood environmental cues, distinguishing

between harshness and unpredictability, predicted precarious behaviors in adulthood. He used longitudinal data to provide evidence that those experiencing unpredictable environments such as changes in residence, employment, and cohabitation status during early childhood (ages 0–5 years old) engaged in riskier sexual behavior and delinquency in early adulthood. Although early childhood environmental harshness did not predict behaviors in early adulthood, studies have shown that both dimensions of environment do indeed provide predictive power in later life (Brumbach et al. 2009; Belsky et al. 2012). These studies suggest that those engaging in these riskier behaviors may require more heightened stress reactivity due to their more perilous activities.

Under a LH perspective, researchers have also emphasized that exerting resources toward the immune system is energetically costly and is largely influenced by an individual's ecology (McDade 2003). Thus, redirecting resources toward reproductive effort, as opposed to maintenance, may be more advantageous under a harsh or unpredictable environment in order to maximize fitness benefits.

Hypervigilance and Psychopathology

While it appears that the accumulation of stress can trigger psychopathological disorders such as anxiety and depression, these mental processes may prove to be context-dependent and central to survival (Frankenhuis and Del Giudice 2012; Nesse 2000). For instance, depressive symptoms appear to serve as a buffer for self-preservation and may have evolved as an adaptive strategy for individuals living in stressful and adverse environments to “prepare for the worse.” Likewise, individuals experiencing anxiety enables them to be alert in situations where alertness and vigilance are favorable attributes that will likely help aid in survival. While it is costly to maintain a heightened state of arousal, it is likely more costly to be unprepared in a situation where the risk for mortality and morbidity are high. These situations are specific to stressful and unpredictable conditions, which are typical to individuals experiencing

discrimination, violence, and disorder. While it is reasonable that threat sensitivity may be the underlying cause to explain the symptomology of psychopathological disorders, it is clear that prolonged and rampant symptoms can eventually lead to mental illness such as major depressive disorder. It is when individuals resort to behaviors and negative thoughts that induce chronic stress, that these symptoms no longer become favorable (Nesse 2000).

Previous research has provided explanations as to why these traits have evolved. Lacking within the literature, however, is empirical evidence clearly justifying potential mechanisms involved with the onset of psychopathological symptoms. A recent study sought to bridge the gap within the literature by exploring the relationship between LH strategies, environmental stressors, psychopathological symptomology, and associated behaviors such as aggression and self-harm (Hurst and Kavanagh 2016). Drawing from various community-based samples, these researchers found a relationship between higher symptomology count and poor parental support correlating with fast LH individuals. These results are in line with previous work by others who have posulated that higher levels of depression are associated with individuals experiencing environmental adversity, all believed to be characteristic of a fast LH strategy (Hurst and Kavanagh 2016). As stated above, it makes logical sense to be hypervigilant particularly in harsh and/or unpredictable ecologies since the future remains uncertain.

Psychosocial Acceleration Theory Revisited

More than two decades has passed since the introduction of the psychosocial acceleration theory. It has gone on to inform countless research studies and other theoretical frameworks. With time, researchers now have a better understanding of the cumulative effects stress has on reproductive success and other LH strategies. To this end, Shalev and Belsky (2016) revisited the psychosocial acceleration theory and proposed its integration with evolutionary theories of aging, focusing

on the downstream consequences of stress on the biological marker of aging, telomeres.

Telomere lengths are repeated nucleotides (TTAGGG) found at the end of each DNA chromosome and serve as protective caps during the DNA replication process (Bodnar 2009). It is a highly conserved sequence whose function is thought to reduce the risk of morbidity and mortality (Monaghan 2010). Much of the literature to date has focused on role of telomere lengths and cancer, but recent studies have now called on evolutionary theories and the integration of physiology and ecology to explain the effects of oxidative stress on development and health (Monaghan et al. 2008; Selman et al. 2012). Furthermore, oxidative stress, which stems from growth and environment, is a metabolic process that occurs when the ratio between free floating radicals (generally unstable) to antioxidants (neutralizes free radicals) are disproportional. These free radicals trigger a chain of reactions that leaves a trail of unstable molecules in its wake and causes extensive damage to cells. Thus, oxidative damage may be one of the factors responsible for the wide variation in telomere loss and may in fact accelerate the rate of senescence (Monaghan et al. 2008).

Previous research suggests that psychosocial stress can alter the rate of telomere loss (Monaghan et al. 2008). Acute stressors have the ability to enhance survival and slow the rate of senescence because the HPA axis is activated for a brief amount of time. However, those living in stressful environments typically engage in chronic stressors and have shorter telomere lengths compared to those living in low stress environments (Epel et al. 2004; Kotrschal et al. 2007; Nettle et al. 2015). Environmental factors have the ability to disrupt the body's defense mechanisms, which ultimately affects the variability in mortality rates (Monaghan et al. 2008).

By combining the psychosocial acceleration theory and research regarding telomere lengths, Shalev and Belsky (2016) proposed a two-hit developmental model of accelerated aging. This model posits that early life adversity and early maturation (leading to earlier reproductive behaviors) interact to predict accelerated aging due to a

fundamental cost-benefits analysis. This interaction is also mediated by biological processes central to the stress profile (i.e., HPA axis, inflammation, metabolism). Early life stress leads to an increased stress reactivity associated with physical health and psychological consequences (as previously mentioned), which likely decreases the lifespan. Additionally, early reproductive behavior requires an extensive amount of energy, which then takes away any kind of somatic maintenance and contributes to a decrease in longevity. If the primary goal is to reproduce, then individuals may incur these costs regardless, in order to ensure the success of passing down genes to the next generation. Thus, the rationale behind the two-hit developmental model of accelerated aging provides a detailed mechanistic approach mapping out the long-term effects from early childhood stress (Shalev and Belsky 2016).

Conclusion

Overall, a LH perspective offers an alternative approach to understand the adaptive function of stress reactivity as it relates to physical health, psychosocial stress, psychological disorders, and accelerated aging. A recent review examining glucocorticoids and its correlates between LH trade-offs through reproduction and survival concluded that this relationship is more complex than previously thought and the evidence to suggest its associations offer equivocal evidence, at best (Crespi et al. 2013). In a field that has capitalized on various theoretical models, future directions should seek to provide empirical evidence for these models. In conclusion, there is much work to be done regarding stress reactivity under the umbrella of LH Theory and many exciting questions that remain unanswered.

Anxiety; Green exercise; Meditation; Mindfulness; Positive psychology

Introduction

Approximately 18% of persons in modern societies experience a mental illness that would meet standard diagnostic criteria of the DSM in any given year; anxiety and mood disorders are the most prevalent (National Institute of Mental Health 2017). Prevention and improvement of mental health status has been the subject of considerable research. Empirical investigation supports several lifestyle interventions that reduce stress and appear to generally benefit overall mental health. These interventions include meditation, exercise, and attention shifts to positive events.

Evolutionary psychologists generally conceptualize mood and emotions as evolved mechanisms to influence behavioral tendencies. Modern life often features combinations of multitasking, serial relocations, high levels of noise, and a sedentary lifestyle, things that would be uncommon or which would be associated with upheaval or illness in hunter-gatherer societies. Modern, industrialized lifestyles may present challenges for the evolved adaptations of the mind

that increase general levels of stress and present risk to well-being. Subjective feelings of stress and mood disorders may be partially a mismatch of evolved mechanisms to expected environments compared with the challenges of modern life (Grinde 2002). Research exists that may provide guidance on alleviating the high levels of anxiety, stress, and negative mood found in modern society.

Meditation and mindfulness. Meditation and mindfulness-based stress reduction (MBSR) appear to reduce stress and increase physical and mental well-being (Krisanaprakornkit et al. 2006). MBSR and the similar mindfulness-based cognitive therapy feature the practice and acquisition of nonjudgmental awareness of current perceptible mental states through focused training. Common techniques include focus on breath awareness under a set of specific instructions designed to increase the narrowness of attention. A meta-analysis of 115 randomized clinical trials (over 8000 total participants) provided evidence of a clear benefit on stress reduction as well as alleviation of depression and improvement in quality of life (Gotink et al. 2015). Earlier research and meta-analyses has also found evidence that mindfulness-based techniques reduce stress and benefit mental health (Grossman et al. 2004).

Green Exercise. Researchers have considered the effects of exposure to nature on mental health. The effect of exercise in the presence of nature (something modern society tends to lack but would be common in environments of evolutionary adaptation) has also been found to reduce stress and improve mental health. A meta-analysis of 10 studies (over 1000 participants) found that exercise in nature improved both general mood and measures of self-esteem (Barton and Pretty 2010). Interestingly, there was evidence that inclusion of water features (e.g., an ocean front or a stream) resulted in greater effect sizes. It appears that the level of the color green itself in a natural setting predicts better mood and tends to lower an individual's perceptual awareness of physical exertion, even when actively exercising (Akers et al. 2012).

Gratitude expressions. Investigations sometimes grouped under the heading "Positive

This article is an overview to empirically-validated behaviors and life-style interventions that impact mental health, broadly defined. Effects related to diet, conventional therapy, and/or medical interventions are not included in this section. Theoretical connections regarding the risk of mental illness related to mismatch between environmental of evolutionary adaptation and modern life are mentioned.

Psychology” are also relevant. By investigating which kinds of activities increase positive emotions, the outcomes measured in such research have also spoken to mental health overall. Interestingly, there is evidence that becoming more aware of and expressing gratitude causes large increases in outcomes related to mental health. Specifically, Seligman and colleagues (2005) assigned participants to placebo or active conditions and found effects on mental health. Daily journaling about specific good events in a day including thoughts about likely causes of those good things, and writing and delivering letters expressing gratefulness to someone who had shown them kindness significantly decreased feelings of depression, and improved feelings of self-esteem. Such reflections may be relatively absent in modern society but appear to be important to mental health.

Conclusion

Evolutionary psychology offers concrete advice of theoretical understanding regarding stress reduction and mental health.

Synonyms

Altruistic rewarding and punishment; Costly rewarding and punishment; Indirect reciprocity

Definition

A combination of a tendency to reward others for cooperation and of a willingness to impose sanctions on norm violators at the strong reciprocator's own cost, even in the absence of future material return.

Introduction

The theory of strong reciprocity is regarded today as one of the most influential attempts at explaining the evolution of human cooperation and altruism (Bowles and Gintis 2011; Fehr and Fischbacher 2003, 2004; Fehr et al. 2002; Fehr and Gaechter 2002; Fehr and Gintis 2008b; Fehr and Henrich 2002; Fehr and Rockenbach 2004; Fowler 2005; Gintis et al. 2003, 2008b; McElreath et al. 2003). Strong reciprocity may take both positive and negative forms. A person is a strong *positive* reciprocator if he/she is willing to sacrifice resources to reward someone else who cooperates, that is, to practice *altruistic rewarding*. In the case of strong *negative* reciprocity, the individual who prefers cooperation is willing to sacrifice resources in order to punish or sanction those who free ride on others, thus practicing *altruistic punishment*. These forms of behavior cannot be explained by self-interest and point to the existence and motivating role of *other-regarding preferences* and *moral norms* in human social exchanges (Gintis 2000, 2008, 2009; Gintis et al. 2008b).

Experimental Evidence

Strong reciprocity has been widely documented in multilateral experimental situations. These typically resemble *social dilemmas*: *n*-person situations in which everyone would gain by cooperation but each individual has an incentive to gain at the expense of the others. The behavior that would be beneficial for all is less profitable for the individual than the selfish alternative, yet it would severely harm the interests of the community if everyone followed self-regarding strategies (Gintis 2009; Van Lange et al. 2007; Van Lange and Joireman 2008; Van Vugt and Van Lange 2006). The *public goods game* is one of the most widely applicable models for such dilemmas (Bowles and Gintis 2011; Camerer and Fehr 2004; Fehr and Gächter 2002; Gintis et al. 2003). This game typically consists of more than one round, in groups of $2 + n$ players. In each round, the players are provided with a certain amount of money, and they have to decide how much of it (if any) to contribute to a common account (i.e., the public good) and how much to keep in their own private account. The individual contributions are summed up and multiplied by a factor of usually three. The resulting sum is then equally divided and added to the players' private accounts, independently of their individual contributions. In public goods games without costly punishment opportunity, the amount contributed to the public good gradually declines over time, which can be explained by the fact that those players who are inclined toward strong positive reciprocity do not cooperate at any cost – their cooperation is conditioned by the other group members' behavior. In the absence of other options, they signal their dislike of the free riders' strategy by lowering their own contributions. If, however, the players are given the option to use targeted, costly punishment against each other, the game unfolds differently. Sanctioning behavior follows the principles of strong negative reciprocity; the players who impose punishment even at their own expense are those who have an initially cooperative approach to the situation; sanctions are used against those participants who contribute nothing or only substandard amounts to the public

good; and, the existence of punishment opportunities results in a stable and high level of contributions, thus re-establishing cooperation. Thus, by acting to raise the level of contributions to the public good, altruistic punishment itself serves as a so-called second-order public good (Bowles and Gintis 2011; Fehr and Fischbacher 2005; Fehr and Gächter 2002).

Strong reciprocity has been widely observed in dyadic experimental setups, as well. In the *ultimatum game*, two players decide over the division of a fixed sum of money. Player A can make one proposal to player B, who can accept or reject it. If B accepts the proposal, the money is shared accordingly; if B rejects, both players receive nothing. Since the game is one-shot and anonymous, the self-interested outcome would be for player A to offer the lowest possible amount and for B never to reject. However, this outcome is almost never achieved: player Bs typically reject offers lower than 30%, regarding them as unfair, and, anticipating this, player As typically offer around 50% (Fehr and Fischbacher 2005; Gintis et al. 2003).

In the ultimatum game, player Bs are directly affected by player As' proposal. There is evidence, however, that a number of people are willing to employ altruistic punishment against those who behave uncooperatively toward a third person (Fehr and Fischbacher 2004). In the *third-party punishment game*, players A and B take part in a *dictator game*. It has the same structure as the ultimatum game, except that here player B has no option of rejecting A's proposal; she/he has to accept whatever is offered. The game is anonymously observed by player C, who is not affected by payer A's decisions. However, C is endowed by a fixed sum of money and has the opportunity to impose a fee upon A after witnessing A's offer. The fee is costly, for the one-third of the decided amount is deducted from C's initial endowment. Nevertheless, in the experiment (Fehr and Fischbacher 2004), 55% of Cs punished A for offers below 50%, and the amount of punishment increased with the perceived unfairness of the offer. This tendency of

disinterested third parties to use altruistic punishment is in line with the supposed role of strong negative reciprocity as a norm enforcement device in real-life situations, e.g., in the upholding of food sharing norms in hunter-gatherer societies (Bowles and Gintis 2011; Fehr and Fischbacher 2005).

Proximate Mechanisms

It has been suggested that in the experimental scenarios described above, the sole motivation for sanctioning behavior is the punishers' desire to maximize their payoffs relative to the punished individuals (Price et al. 2002). However, there is evidence indicating that this is not the case. In a prisoner's dilemma experiment by Falk et al. (2005), the cost of punishment was the same for the punisher and the punished player, so it was not possible to influence and affect the difference in payoffs via sanctioning. However, almost 60% of players who cooperated in the game imposed substantial amounts of punishment on defectors. Moreover, strong reciprocity has been observed in one-shot experimental scenarios where costly rewarding or punishment holds no possibility of long-term economical benefits for the strong reciprocator. It seems that strong reciprocity is to a large extent motivated by the negative emotions strong reciprocators feel when observing unfair decisions and the positive emotions induced by their own sanctioning behavior as well as by their cooperating with other cooperators (Bowles and Gintis 2011; Declerck et al. 2013; Fehr et al. 2002; Fehr and Camerer 2007; Rilling et al. 2002). Studies combining neuroimaging methods with economic games have shown that both first-person and third-person punishment behavior activate reward-related brain regions (De Quervain et al. 2004; Strobel et al. 2011). Thus it seems that humans are endowed with proximate mechanisms in the form of social preferences and moral emotions that render both strong positive and strong negative reciprocity pleasurable even when it yields no financial gains.

Evolutionary Origins

Costly punishment might feel good, yet the finding that it is not the most economically beneficial strategy in public goods games (high contributors, who neither receive nor give out punishments, are the most successful) raises the question of the possible evolutionary origins of such an altruistic strategy. The answer may be found in the theories of multilevel selection and gene-culture coevolution. According to the literature (Bowles and Gintis 2011; Gintis et al. 2003), in the relevant evolutionary period of the Pleistocene, intergroup competition constituted a formidable force in the dynamics of human evolution. Human groups often had to face dispersal or extinction threats due to wars, famines, environmental disasters, etc. Groups with a relatively high proportion of strong reciprocators enforcing cooperation norms were much more likely to survive such events. Moreover, humans have unique cognitive and emotional capabilities enabling us to create and communicate social norms, among them norms of altruism, cooperation, and the suppression of within-group competition. In such circumstances, within-group selection forces acting against strong reciprocators weaken to the extent that eventually they invade a population of self-regarding types (Bowles and Gintis 2011; Fehr and Fischbacher 2005; Gintis et al. 2003; Richerson and Boyd 2004). The use of moralistic punishment as a norm enforcement device may spread among the members of an entire population through the mechanism of conformist transmission, the behavioral norm of imitating the most successful members in a community (Bowles and Gintis 2011; Richerson and Boyd 2004).

It is worth noting that strong positive reciprocity seems to be evolutionarily less stable than strong negative reciprocity. Whereas the costs of altruistic punishment decline as the number of free riders in a group diminishes, the cost of altruistic rewarding is independent of the number of free riders. Thus, when strong negative reciprocators are common in a group, there are only weak selection forces operating against them, and their

presence allows cooperation to become a stable strategy even within larger groups (Gintis et al. 2003).

The above claims are disputed by those who hold that strong reciprocity is a maladaptive behavior stemming from the differences between the environments relevant for human evolutionary history and those of contemporary modern societies and of the experimental situations. Specifically, this argument states that the human mind is not adapted to deal with anonymous, one-shot scenarios among strangers and treats them as if they were unanimous, repeated interactions among acquaintances. However, there is ample evidence that humans are able to distinguish between friends and strangers and between one-time and repeated interactions and to change their behavior accordingly. Thus, it seems unlikely that the maladaptation theory can account for strongly reciprocal behavior (Fehr and Henrich 2002; Gintis et al. 2003).

Conclusions

Strong reciprocity, the propensity to sacrifice resources in order to reward cooperation and punish free riding, is a well-documented factor in experimental scenarios and may have played a crucial role in the evolution of human cooperation itself. The main motivation behind this behavior lies in proximate mechanisms shaped by evolutionary forces and conditions that rendered this behavior, in spite of its costs, invaluable in the upholding of social norms.

Definition

The study of natural history, behavioral ecology, and evolution of dunnocks, *Prunella modularis*, with respect to their intriguing mating behaviors.

Introduction

A mating system is a description of the processes by which males and females acquire mates. Mating systems are generally stable within and among populations of a species. For instance, most avian species could be described as socially monogamous, meaning that males and females form pairs during the breeding season to mate and, occasionally, to raise young together. Within this typical bird population, most individuals would breed as pairs.

At least since the 1950s (Campbell 1952), bird watchers and researchers suspected that a little dull brown bird, the dunnock, *Prunella modularis*, would hold some surprises about their mating behaviors. But it was not until the 1980s that studies using color-banded individuals (i.e., marked with a unique combination of colored plastic rings on their legs) provided insights about the curious mating behaviors of dunnocks. These studies (Birkhead 1981; Karanja 1982) confirmed what was suspected since at least the 1950s; dunnocks presented considerable variation in mating combinations. Far from the usual monogamous bird species, dunnocks presented within-population variation in mating patterns. Dunnocks breed as pairs (monogamy), groups of a male with two females (polygyny), a female with two or more males (polyandry), or even groups of two or more males sharing several females (polygynandry) (see Davies 1992). Such within-population variation in mating patterns is unique across animals, making the dunnock an interesting study system for understanding the evolution of mating systems.

Dunnocks are also known for a peculiar sexual behavior, first described in 1902 by the ornithologist Edmund Selous. The behavior – named cloaca pecking – is part of the precopulation display performed before a copulation attempt. During this display, the male hops around behind the female while she shudders her wings and raises her tail to expose her cloaca (see Davies (1992) for a thorough description). The male will then peck at the female's cloaca several times within a minute before he copulates with her.

Occasionally, the female will dip her abdomen and eject a droplet of sperm. Males only copulate after females eject this droplet. Nick Davies (see Davies 1992) interprets the behavior as a female attempt to convince the male that he has a chance of gaining paternity. Consequently, encouraging him to stay with the female and provide care toward her young. Davies' interpretation makes sense because social polyandry is a common mating strategy in dunnocks. That is, in social polyandry, females are simultaneously paired with two or more males that copulate with her.

Once these naturalistic studies identified that dunnocks possessed a variable mating system – that is, one in which there was variation in the mating compositions – the focus shifted toward hypothesis-driven studies based on theory. Davies, who was one of the founders of the field of Behavioral Ecology, employed evolutionary theory to investigating the variable mating system of dunnocks (see Davies 1992). The long-term study by Davies in England has helped us to understand many aspects concerning dunnock mating behavior and contributed to the field of behavioral ecology in general. For instance, Davies' study provided understanding of parental investment and sexual conflict theories (see the section "[Cross-References](#)"). Davies' studies have become a textbook example of mating systems. More recently, another study – using an introduced population in New Zealand (see Santos (2012) for details about the introduction history of dunnocks) – has also investigated the mating system of dunnocks to address behavioral and evolutionary questions. These recent studies have found several new facts and unexpected insights into dunnock mating behavior (see below).

Variable Mating System

The Cambridge (see Davies 1992 for details) and the Dunedin (Santos et al. 2015 and references therein) studies provide information on the formation of the different mating types. Apparently, the mating combinations are a consequence of variation in male and female territory size,

and competitive ability of individual birds. Unlike other birds, female dunnocks do not choose males based on their territories or territorial attributes. Females appear to choose their breeding territories independently of males, and female settlement is based on competition with other females for space. Thus, a mating combination – for instance, monogamy – is the result of a small female territory and a male with enough competitive ability to ward off male intruders. Social polyandry is likely to result from a large female territory that overlaps with at least the territories of two males. These males, in turn, chase the female around her territory, while fighting with each other. These male-male interactions result in a dominance hierarchy, and then these males coalesce their territories.

In the Cambridge study, territory size was different between polyandry (0.71 hectares) and monogamy (0.28 hectares). Meanwhile, in the Dunedin study, polyandrous and monogamous groups had similar-sized territories (0.24 hectares) (Santos and Nakagawa 2013). Thus, it seems that while in Cambridge female territory size is an important characteristic shaping the variable mating system, in Dunedin it seems that female territory size may play a smaller role.

Both studied populations presented male-biased adult sex ratios, that is, there were more adult males alive during the breeding season than adult females. In Cambridge, males represented 54.5% of adults, while in Dunedin males represented 57% of breeding adults. Compared to the Cambridge and four other dunnock studies (Davies 1992), the Dunedin population had the highest density of males per hectare, averaging 5 males/hectare, while the Cambridge population averaged 2.6 males/hectare. These demographic differences are probably associated with differences in the frequency of the within-population mating combinations. For instance, in Dunedin – with high male density and skewed sex ratio – territories are small, and social monogamy and polyandry are the predominant mating combinations.

In evolutionary terms, the different mating combinations yield different fitness payoffs to males and females. In species like the dunnock, in which males feed the nestlings, the fitness

consequences of the mating combinations are important to breeding individuals. From a fitness perspective, polyandry is the optimal breeding situation for females because multiple males provide care. Yet from a male perspective, sharing the same female with another male is not optimal. Theoretically, this occurs because a male may lose paternity to his co-breeding male partner. Dunnock mating systems, therefore, are an example of sexual conflict. The development of genetic analyses allowed for the investigation of maternity, paternity, and relatedness between individuals, yielding insights into the consequences of the sexual conflict in dunnocks.

The Genetic Eyepiece

In 1989, Burke and collaborators (Burke et al. 1989) applied a technique called DNA fingerprinting to dunnocks from Cambridge to investigate the relationship between the mating behavior of birds from the different mating combinations and genetic paternity. In social monogamy, all chicks were sired by the resident male. In the polyandrous groups, in which the male hierarchy dictates mating access to females, the dominant and subordinate males split the paternity of broods almost evenly. These findings showed that even with little mating access to the female, subordinate males could gain paternity in polyandrous groups.

Santos and colleagues (Santos et al. 2015) also investigated how paternity was distributed among dunnock broods in Dunedin. In this study, the authors used microsatellite markers to generate individual genetic profiles used to assess paternity and relatedness among dunnocks. The Dunedin study revealed differences in the genetic mating system of dunnocks. While in Cambridge there was little evidence of extra-pair or extra-group paternity – offspring that were sired by males other than the males from the social breeding group – in Dunedin, extra-pair and extra-group paternity was abundant. Extra-group paternity occurred both in socially monogamous and socially polyandrous groups. Over 30% of broods from socially monogamous pairs had at least one chick that was sired by an extra-pair male, while 17% of

broods from socially polyandrous groups had at least one extra-group young (Santos et al. 2015). These data suggest that (i) males in socially monogamous pairs are not as efficient in guarding their mates against intruders as two or more males in socially polyandrous groups; and (ii) females in socially monogamous pairs have more opportunities to leave their territories and engage in extra-pair copulations than socially polyandrous females.

The paternity data from the Dunedin study also changed how we interpreted the reproductive payoffs from a male perspective. Davies and collaborators showed that males had highest reproductive success with polygyny, less with monogamy, and least with polyandry (summarized in Davies 1992). This is the theoretical expectation when males do not lose paternity to extra-pair males. However, in Dunedin, extra-pair or extra-group paternity accounts for the paternity of 23% of young in social monogamy and 10% of young in social polyandry. Considering all the paternity lost and gained by including extra-pair or extra-group paternity in the estimates, Santos and collaborators (2015) showed that the number of young fledged per breeding attempt was similar among three types of males: socially monogamous, alpha, and beta co-breeding males. Thus, from a male perspective, sharing a female with another male in a socially polyandrous group is not such a bad reproductive tactic.

Moreover, the Dunedin study has also showed that when females engage in multiple mating that leads to mixed-paternity clutches, they avoid negative effects caused by inbreeding. Additionally, an increase in the relatedness between breeding males and females in social monogamy decreases hatching success of the eggs. The relatedness between individuals had another biologically relevant consequence. Many male coalitions in polyandrous groups were closely related in Dunedin; that is, their relatedness estimates ranged from cousins to offspring/full-sibling. The consequence of breeding together for these closely related males is that they also gain indirect fitness benefits (estimated at approximately 5% of their direct reproductive success). In Cambridge,

through detailed observations, Davies and colleagues did not observe any instance of closely related individuals breeding together.

Personality and Its Implication for Dunnock Mating

Another study in Dunedin has investigated the relationship between “personality” genes and behavior. Among other findings, Holtmann and collaborators (2016) found significant allele effects for the association between the mating status of a dunnock and its genotype at two “personality” genes. These genes are the serotonin transporter gene (*SERT*), for which allelic variation has been associated with several behavioral phenotypes in other species, and the dopamine D4 receptor gene (*DRD4*), in which variation is associated with exploratory behavior and activity in vertebrates. Mating status was defined as the individual’s social mating composition. This study classified individuals into four mating statuses: (i) monogamous females, (ii) monogamous males, (iii) polyandrous females, and (iv) co-breeding males. These categories represent the different degrees of promiscuity exhibited by individuals. Individual mating status was repeatable across three breeding seasons, meaning that birds were consistent with respect to their mating categories. The intra-class correlation (i.e., repeatability) of male mating status was on average of 73%, while female mating status had an intra-class correlation of 60%. Notably, males that were homozygous for two *SERT* alleles (namely SNP840 and SNP966, see Holtmann et al. 2016) were on average 27% more likely to form a coalition with a co-breeding male than heterozygous males at these alleles. Overall, these findings indicate that genomic information will become an increasingly important tool in the study of mating systems.

Conclusion

The study of dunnock mating started with curious naturalistic observations. When these naturalistic

observations were acknowledged and studied in a systematic manner, dunnocks became a textbook example of a unique mating system and shed light on several important theoretical areas. It is through the combination of naturalistic observations, a theoretical foundation to stimulate study questions, and long-term studies that what could have been an anecdotal observation of a little brown bird became an essential asset in behavioral ecology and evolutionary biology.

Genetic codification of behavior; Innate; Nativism

Definition

Patterns of behavior that emerge in the absence of relevant related experience, usually taken to be species-specific and genetically encoded.

Introduction

Historically, the study of behavior has been centered around a strong opposition between instinct (or nature) and learning (or nurture). The “instinct” concept was (and still is) adopted in many fields (Psychology, Ethology, Biology, Linguistics, etc.) as an explanation for the complex behavioral patterns exhibited by most species; when in the absence of relevant external influences, these appear to be internally driven. It is routinely suggested that such cases point to some kind of internalized knowledge. In contrast, learned behaviors are those thought of as being acquired from externally experienced models.

The following paragraphs first introduce the conceptual bases of the “instinct” concept as originally elaborated within the ethological tradition,

and then go on to explain the many shortcomings of the concept that have been alluded by the developmentalist alternative to that tradition.

Arguments for the “Instinct” Concept

The “instinct” concept has a long pedigree. It played an important role in the early evolutionary approaches to the psychological makeup of species by the likes of Erasmus Darwin, Pierre Jean George Cabanis, Jean-Baptiste Lamarck, or Charles Darwin, but its definitive incorporation into the natural sciences is mostly due to the European ethological tradition and the influential figure of Konrad Lorenz. This ethological trend transformed the classical, mostly metaphysical nativist stance into a theory of instincts, that is, of the behavioral reflexes of an evolved species-specific genotype.

According to this tradition, genes play a central role in the explanation of inborn behaviors. In the words of Lorenz, instincts are “a certain type of innate, genetically determined behavior patterns” (Lorenz 1950, p. 221). Correspondingly, a gap is said to exist that distinguishes genetically and experientially determined behaviors – i.e., instinctive and learned conducts. Within this conceptual frame, instinctive behaviors are species-specific in the same sense as morphological features like dentition or claws (Lorenz 1950, p. 238), since they all belong to a pre-specified functional plan of the species.

Instincts are believed to exhibit intrinsic design qualities, for which natural selection is the only reasonable source of explanation (Lorenz 1965). As a matter of fact, ethologists pioneered the application of Darwin’s theory in recent times, following a path that Darwin himself had opened. Furthermore, instincts typically manifest “critical period” effects, and they fix and become endurable in the absence of correlating perdurable stimuli. Instincts may take some time to show up for the first time but, according to Lorenz, far from being the result of a period required for learning the corresponding behavior, such delays are due to mismatches between the instincts themselves and the maturation of the organic systems in charge of their execution.

Lorenz always held a geneticist stance regarding the causal explanation of instincts. However, in the 1960s, he partially qualified his position, clarifying that what is in fact innate are not the behaviors themselves, but the information that underlies them. From that point on, innate features were defined as “coded information stored in the genes” (Lorenz 1965, p. 20), so “organs or behavior patterns must not be called innate” (Lorenz 1965, p. 34). Within this reframing, Lorenz also reformulated the “instinct” versus “learning” distinction, now asserting that the difference refers to the different timescales within which the corresponding sources of information act: instincts correspond to adaptive information which is stored in the genome by natural selection, and learning corresponds to adaptive information which is directly provided by the environment and assimilated during the life cycle. Instincts thus develop under strict genetic control (Lorenz 1965, p. 103).

Such a gene-centric turn is certainly neo-Darwinian in spirit, as it adheres to the usual logic according to which “the genes of an organism are present at its conception, and so its innate traits are also present at the conception, even though only in coded form” (Mameli and Bateson 2011, p. 438). Actually, Lorenz adhered to the notion of a “genetic program” that contains a draft of the whole developmental process of a given organism: “What rules ontogeny, in bodily as well as in behavioral development, is obviously the hereditary blueprint contained in the genome and not the environmental circumstances indispensable to its realization. It is not the bricks and the mortar which rule the building of a cathedral but a plan which has been conceived by an architect” (Lorenz 1965, p. 42).

The “Instinct” Concept: Arguments Against

The notions of “nativism” and “instinct” are not straightforward ones, for they actually mix distinct nonequivalent meanings (Lorenzo and Longa 2018). If anything, they might be treated as conceptual clutters, in the sense of Mameli and

Bateson (2011). Moreover, an increasingly influential developmentalist trend rejects these notions because (1) nothing organic can avoid some kind of constructive developmental path, and because (2) they discourage the study of such paths (Blumberg 2005; Moore 2001). In the critical words of Blumberg, “why discuss development when all of the interesting behaviors are inborn, programmed in the genes, preordained!” (Blumberg 2005, p. 13).

The idea of instinct disdains, according to the same trend, the far-from-trivial influence of prenatal experience on mature capacities. Zing-Ying Kuo famously showed that the pecking behavior of chickens is grounded on the prenatal activity of the embryos, where every single component piece of the total behavior (head movement, bill opening and closing, swallowing, etc.) is already attested. Thus, according to Kuo, “the development of behavior is a gradual and continuous process, and not a sudden manifestation of instincts” (Kuo 1932, p. 109). In a similar vein, Gottlieb showed that prenatal experience paves the way for postnatal conducts (Gottlieb 1997): e.g., birds fostered in incubators show a preference for the maternal calls, because chicks practice similar calls before hatching.

Daniel Lehrman criticized the relevance with which Lorenz credited isolation experiments, which are based on the logic that if an animal bred in isolation exhibits a certain behavior, such behavior must be impressed on the genome. According to Lehrman, such experiments discard only some influences (e.g., frank learning or learning from conspecifics), but not others, somehow less obvious. Thus, he concluded that “The important question is not ‘Is the animal isolated?’, but ‘From what is the animal isolated?’” (Lehrman 1953, p. 343). Experiments based on this logic offer little information regarding the factors actually involved and regarding the comprehension of what development ultimately is. Many so-called instinctive behaviors are simply due to the fact that conspecifics develop in the same environment and share the same action system (Kuo 1921; Lehrman 1953).

In any event, the central point of the developmentalists’ criticism has to do with the

instinctivists' dismissing the idea that development means "the increase of complexity" (Kuo 1921, p. 663), an objection also raised by Lehrman (1953). According to Lorenz, the development of behavior follows inflexible and immutable paths, strictly fixed and informed by the genes. He claimed that development was simply a progression toward the revelation of the instinctive conduct, and not a historical process during which behavioral repertoires are constructed. Lehrman argued against this view, because it ignores the fact that rich interactions between organism-internal processes and the environment occur at every developmental stage, creating qualitatively new, or emergent, properties. In his own words, "The interaction out of which the organism develops is not one, as is often said, between heredity and environment. It is between organism and environment!" (Lehrman 1953, p. 345). Indeed, the genes-environment interactions are mediated by many structural components and levels at different developmental stages. Centering the causal explanation of development on just two factors entails neglecting a plethora of other equally relevant ones.

To close, developmental biology shows that the idea that the genes crucially inform development is misguided: "DNA does only one thing: It provides the information needed to produce proteins" (Moore 2001, p. 73). The effect of the genes on the phenotypic outcomes are very indirect, almost negligible if one does not take into account the contribution of the remaining factors that mediate between the genes and the traits.

Attending to all previous reasons, Blumberg concludes that the "instinct" concept "is an illusion" (Blumberg 2005, p. xiv).

Conclusion

How do morphologies and behaviors take shape? Where do they come from? Where do they obtain the information required to attain a steady state? On the one hand, neo-Darwinism relies on an answer to these questions in line with classical preformationist stances, according to which forms are preformed (nowadays,

programmed) in the genome. On the other hand, current developmentalism defends that no single organic trait can preexist their own development and that shape emerges dynamically through qualitative changes. The issue is not a closed one, neither in the case of anatomical nor behavioral traits.

Definition

Stuttering is a disorder of verbal fluency characterized by repetitions and prolongations of sounds and syllables.

Introduction

Effortless concatenation of words with proper cadence and stress pattern to produce utterances is a much taken-for-granted skill. In roughly 1 % of the general population who stutter, this skill is compromised with negative consequences on educational, vocational, and social life.

Developmental Stuttering

Stuttering typically begins during early childhood years between the ages of 2–5 years – a period of rapid growth, especially in language and speech. Most children within the age group occasionally (or intermittently) repeat monosyllabic words (But- but), initial sounds, and syllables of words (ka- car) (collectively called part-word repetition) before producing the target word. Very rarely,

they may prolong initial sounds of words. Clinicians consider both the type and frequency of these occurrences (called disfluencies) and other speech-related features in the context of family history to diagnose the problem of Developmental Stuttering (DS) (Ambrose and Yairi 1999).

Repetitions and prolongations are considered core features of DS (Wingate 1964). Ambrose and Yairi (1999) have shown that the onset of stuttering is typically gradual; however, in a small minority it is sudden; also, onset is characterized by repetitions of initial sounds, syllables, and monosyllabic words. The other defining feature, namely prolongation of initial sounds of words, is generally considered to be red flag for persistency. There is a consensus, based on many studies (Ambrose and Yairi 1999; Mansson 2005) that in nearly 80 % of children DS is self-limiting, that is, recovery occurs naturally or without formal intervention, within a short span after onset (2–5 years). The remaining 20 % who persist continue to stutter and may exhibit a variety of speech and nonspeech (behavioral, emotional) concomitants that need special therapeutic attention from speech-language pathologists. The incidence of stuttering tapers off considerably after the age of 5 years. The challenge to both researchers and clinicians is to arrive at a list of empirically verified criteria that reliably sort out those in whom the disorder is self-limiting and those in whom it is not. A rough outline of an answer to this question is emerging. Thus, recent research indicates that in children who produce multiple irregularly paced repetitions of the initial sound or syllables of words prolongation of the initial sounds are likely to persist (Ambrose and Yairi 1995). A discerning clinician will take into account these findings along with frequency of disfluencies, family history of persistent, and recovery from it to treat/ manage the disorder.

When clinicians refer to stuttering, they generally refer to children with Developmental Stuttering (DS) or older children and adults with Persistent Developmental Stuttering (PDS). Fluent speech can also be disrupted because of brain injury or psychological causes including malingering for financial reasons (financial compensation following accidents). This group is called Acquired Stuttering (AS). These individuals

exhibit many of the defining features of DS; however, they differ from DS in terms of location of disfluencies in sentences as well as how individual disfluencies are produced. Research in this area is very preliminary because AS is very sporadic (Viswanath 2010).

The proximal causes of speech fluency breakdown during stuttering have been investigated using a variety of methods – EMG, aerodynamic, and acoustic representing multiple levels of production process. These investigations reveal the dynamics underlying stuttering episodes (e.g., Viswanath and Neel 1995) but also have shown that imperceptible but significant deviations in speech gestural coordination (temporal and spatial) exists even when stutterers are perceptibly fluent. The tenuous fluency may arguably be the basis of fully elaborated perceivable intermittent interruptions we call stuttering (Viswanath and Rosenfield 2000) and presents assessment challenges to clinicians.

The more distal causes of stuttering, in a sense more fundamental, is the role of genetics and the brain mechanisms underlying stuttering. A general outline of the role of genetics in the development, natural recovery, and persistence is slowly emerging. It was known for a long time that stuttering runs in the families and that boys with DS outnumber girls with DS (3:1). DS aggregates in multigenerational families in rates greater than general population prevalence of 1 %. However, studies of such multigenerational pedigrees showed that the pattern of transmission (so-called segregation pattern) did not fit into one of the well-known, simple inheritance patterns discovered by Mendel. There are studies of multigenerational families (e.g., Viswanath et al. 2004; Ambrose et al. 1997) that suggest a model where a single dominant gene in a multifactorial context (other genes and environment) may be the best account for the disorder. There have been several recent successful attempts to locate the putative gene (s) on chromosomes using linkage and other more recent techniques in genomic science (e.g., Riaz et al. 2005).

A coherent account about stuttering must address the issue of brain mechanism underlying the intermittent disfluencies that we call stuttering events. Recent applications of neuroimaging

techniques – PET (Positron Emission Tomography), Functional Magnetic Resonance Imaging (fMRI), Magneto-Encephalography (MEG) – have revealed tantalizing differences between PDS and fluent speakers in how the brain implements the task of speaking. The activation patterns and the areas of activation in the two hemispheres, basal ganglia and cerebellum, differ between PDS and fluent speakers; stutterers tend to get “normalized” when immediate fluency is induced by such techniques as Choral speech, speaking in unison with metronome beats, or masking noise. Volumetric MRI – that is useful to study fine-grained anatomical differences – has shown gyral pattern differences between the PDS and normal controls around Peri-sylvian fissure in left hemisphere. Perisylvian areas in the left hemisphere is intimately involved in language and speech processing. All these findings are preliminary – they provide an impetus for developing models of mechanism of stuttering events (Ingham et al. 2003). A coherent and complete account will also provide the pathway(s) from gene (s) and its products (proteins coded) and products’ effect on brain development and functioning that leads to atypical functioning and observable disfluencies.

In the absence of understanding of causal basis of the disorder, current approaches to therapy focus on using behavioral (symptom management) and cognitive therapy techniques. There is generally a consensus that early intervention in young children is preferable to no treatment despite high rates of natural recovery. Modalities of therapy with adolescent and adult stutterers vary with the nature of behavioral and emotional overlay an individual presents. Techniques to modify disfluencies by altering speech pattern coupled with behavioral techniques to eliminate avoidance and escape behaviors that persistent developmental stutterers exhibit is the main focus of therapies in adults.

Conclusion

Stuttering is an early childhood disorder that emerges during rapid growth of language and speech. Recent research shows that it is a

biologically inherited disorder with significant learning component. Eighty percent naturally recover; in the remaining 20 % it becomes persistent disorder with negative impact on vocational and personal life.

A cultural subgroup within a larger culture is defined as having some behaviors, beliefs, or interests different from the mainstream culture.

Introduction

The concept of *subculture* was initially developed in sociology and anthropology (Berzano and Genova 2015). *Counterculture*, on the other hand, refers to a particular type of subculture whose values and behaviors differ substantially from those of mainstream culture, being in opposition to mainstream culture values and behaviors (Hirsch et al. 2002). An example of counterculture may be the hippie subculture during the 1960s and 1970s.

Subculture Characteristics

The concept of subculture began during the early twentieth century. It is related to Durkheim's

sociology (Durkheim 1895) and the so-called Chicago School (Park and Burgess 1921). This concept has been used by a diversity of disciplines, including sociology, anthropology, psychology, and criminology. However, it has been most influential in sociology and criminology as a major explanatory tool to comprehend deviant behaviors (Blackman 2014).

A diversity of subcultures have been described, including subcultures according the age (e.g., youth subculture, aging subculture), gender, place of living, professional activity, illegal groups, economic status, educational level, and others. Nonetheless, the concept of subculture has been frequently used to interpret deviant behaviors. Within criminology, the concept of subculture has been usually interpreted as dysfunctional, inappropriate, and delinquent.

During the 1970s, the Centre for Contemporary Cultural Studies (CCCS) (Hall and Jefferson 1975) redefined the analysis of subcultural studies, youth, and deviance. The new approach on deviant behavior interpreted subcultures in terms of their engagement in resistance and social opposition. Different studies, particularly in England and the USA, have analyzed the characteristics of youth subcultures particularly with regard to deviant behaviors (Blackman 2005; Williams 2007). Currently, and given our contemporary technological conditions, it has been suggested that diverse social media (internet, virtual reality, games, etc.) have promoted the emergence and development of diverse new subcultures among the young generation (Zhao et al. 2017). Gender, ethnic, and even hobbies preference subcultures have been described in youngsters (Hollingworth 2015).

Other studies have emphasized the regional subcultures. As an illustration, Neapolitan (1994) analyzed the Latin American subculture of violence, and relate it with cultural values that have evolved out of the history of colonization and subjugation that is shared by most Latin American nations.

A subculture of education has been proposed since long time ago (Vygotsky 1930/1980). Education develops some specific values and reinforces certain patterns of behavior, and

hence, a subculture of education can be distinguished. Recently, Venuleo et al. (2016) tested the hypothesis that educational subculture in terms of which students interpret their role and their educational setting affect the probability of dropping out of higher education. Results demonstrated that the probability of dropping out is significantly associated with students' educational subculture – but not with their incoming level of knowledge and skills. Similarly, diverse living characteristics in different working and socioeconomic conditions are correlated with some specific values and behaviors. Riessman and Miller (2017), as an illustration, analyzed the working-class subculture. The nature of the conditions of working-class lives (jobs, opportunities, and family structure) affects values, attitudes, and behaviors. As an important element, coping with, the instability threats becomes a dominant activity and core element within the working-class family; specific practices, such as mutual aid and cooperation, extended family perspectives, are important as coping mechanisms found in this working-class subculture.

Similarly, a subculture of poverty has been described in anthropology (Lewis 1959; Wilson 2016). This subculture has some very specific values including helplessness, the search for immediate gratification, dependency, marginality, and powerlessness. The notion of a subculture of poverty, however, sometimes has been considered to be simplistic.

Conclusion

In every culture, variations are observed. When some behaviors, beliefs, and values are different enough from the mainstream culture, we can refer to a subculture. The concept of subculture began in sociology during the early twentieth century and has been sometimes associated with deviant and delinquent behaviors. However, diverse subcultures can be distinguished departing from different social, anthropological, and psychological variables: age subcultures, gender subcultures, professional subcultures, regional subcultures, etc.

Definition

A class of mental disorders characterized by compulsive seeking and use of mind-altering substances despite experiencing severe negative consequences.

Introduction

The nature of substance use disorders (SUDs) has changed exponentially over the years with the development of novel and highly potent synthetic formulations and creative methods of ingesting substances to achieve a variety of euphoric effects (Lovrecic et al. 2019; United Nations Office on Drugs and Crime 2017). The global burden of SUDs has reached epidemic proportions for some classes of substances with unprecedented deaths from opioids prompting the declaration of a public health epidemic in the United States (Kanouze and Compton 2015; Kolodny et al. 2015; Rudd et al. 2016; United Nations Office on Drugs and Crime 2017). Integrated biopsychosocial models of the development and perpetuation of SUDs have enhanced our understanding of what many in the scientific community consider a chronic and progressive brain disease (NIDA 2018; Volkow et al. 2016). While effective pharmacological, motivational, and cognitive-behavioral interventions for SUDs exist and are widely available (Carroll and Kiluk 2016), the SUD problem persists and does not seem to be going away any time soon. Evolutionary theories may add a much-needed perspective to help understand and inform the prevention and treatment of SUDs.

This entry reviews three major evolutionary theories of SUDs (i.e., Mismatch Theory, Life History Theory, and False Fitness Theory) directed at understanding how our ancestors used substances to solve problems and protect the species, the mechanisms that evolved to make modern human beings susceptible to SUDs, and reasons natural selection has not eliminated vulnerabilities to developing SUDs. The entry also applies the evolutionary perspectives outlined above to understanding the ontology of SUDs and the major proximal processes, mechanisms, and behaviors associated with compulsive drug seeking.

Evolutionary Benefits of Naturally Occurring Substances

According to Hagen and Sullivan (2018), humans evolved adaptations for detecting, avoiding, and

neutralizing plant toxins through a billion-year arms race with their defenses. For millions of years, our primate ancestors fed on plants that leveraged toxins to ward off predators. Today, humans are armed against plant toxins with defenses such as bitter taste; tissue barriers (e.g., in the gastrointestinal tract); and nausea, vomiting, and conditioned taste aversion. These systems could only have evolved given a long evolutionary history of human exposure to and interaction with plant toxins. That humans correctly identify drugs as aversive toxins, yet find them rewarding enough to seek out and consume, is “the paradox of drug reward” (Hagen et al. 2009; Sullivan and Hagen 2002; Sullivan et al. 2008). Below we review some of the possible fitness benefits of various psychoactive substances in response to this paradox.

First, humans may have evolved to metabolize alcohol through consuming overly ripe and fermented fruits (Dudley 2002). Continued ingestion of overly ripe and fermented fruits and psychotropic plant substances at low, nontoxic doses may have enhanced physical health, performance/endurance, cognitive functioning, and social relationships (for reviews see Davis 2014; Dudley 2002; St John-Smith et al. 2013). Indeed, alcohol improves mood, induces mild euphoria, and increases confidence, sociability, communication and intimacy (helpful for mating/reproduction); moreover, it is an anxiolytic, aids in sleep, and serves as an antibiotic and, in the past, an anesthetic (for reviews see Davis 2014; Nace 2016; St John-Smith et al. 2013).

Cocaine, caffeine, and nicotine increase energy, stamina, alertness, and attention, which may have afforded an advantage in hunting, foraging, and protecting next of kin (Davis 2014; Juliano and Raglan 2016). Cocaine may have also served as a local anesthetic and an appetite suppressant during times of famine, and opioids, found naturally only in trace amounts, may have served as a pain reliever and sleep aid (for a review see Davis 2014). Hallucinogens may have facilitated group cohesion and bonding (St John-Smith et al. 2013). Moreover, people may have deliberately sought compounds found in psychotropic plants for medicinal purposes

(Ben Amar 2006; Davis 2014). Tobacco and cannabis may have helped ancestral humans reduce pathogen load, and consumption of plant neurotoxins may have prevented or treated macro-parasite infections (Hagen et al. 2013). For example, both tobacco and cannabis use appear to ward off helminths (Roulette et al. 2014, 2016).

From an evolutionary perspective, our ancestors may have been able to maximize fitness and survival success by ingesting naturally occurring substances at low levels that did not result in impairment or harm. However, modern technological advances in the production and administration of highly potent substances have led to an evolutionary mismatch and the development of SUDs, which “has no adaptive value” (Hill et al. 2017, p. 142).

Evolutionary Mismatch

According to mismatch theory, pathology stems from the adverse effects of modern environments on evolved traits that were once adaptive (Li et al. 2018). Human intelligence has led to innovations in every facet of life – medicine, technology, food production, transportation, climate control, leisure, etc. (Buss 2000). The human capacity for innovation has extended our longevity, dominance over other species, and has led to the massive migration and propagation of our species. Unfortunately, some innovations have resulted in many unintended consequences including propagating the public health crisis of SUDs (Buss 2000).

Synthetic opioids, initially conceived with the intention of alleviating chronic pain, have morphed into deadly addictions in vulnerable individuals. The development of syringes to deliver medications has contributed to more addictive and lethal means of ingesting addictive substances. Modern-day manufacturing and distribution of substances (e.g., distillation and purification of alcohol; engineering of synthetic drugs without plant cultivation) has led to a major strain on what our ancient brains were naturally evolved to handle (Davis 2014; St John-Smith et al. 2013; Li et al. 2018; Nesse 2002; United Nations Office

on Drugs and Crime 2017). Technological advances and the development of virtual online pharmacies have promoted aggressive and sophisticated marketing techniques, flooding global markets with hundreds of highly potent novel psychoactive substances, including synthetic amphetamines and cannabinoids (Dignam 2017; Schifano 2018).

The change from an ancient environment of very limited resources to a modern world where basic needs are generally satisfied and hedonic desires are easily fulfilled has taxed self-control abilities that were untested or unnecessary in ancient times (Lende 2008). The higher potency of manufactured substances has bypassed defenses or regulatory mechanisms that would have protected our ancestors from developing SUDs. Moreover, insofar as the modern world presents with novel psychosocial stressors, widely available substances may be regularly turned to as a fast acting, albeit maladaptive, coping mechanism, and reward during times of stress (Lende 2008). Indeed, Nesse (2002) has suggested that SUDs may be “a disease of civilization” (p. 471).

Life History Theory

In evolutionary biology, fitness is the average contribution of a genotype or phenotype to the gene pool of the next generation. Life history theory is a framework of trade-offs used by evolutionary biologists to explain differences between species in the manner by which they optimize fitness given the challenges of their particular ecologies (Stearns 1976, 1989). The basic logic of life history theory is that because resources are finite, investments in fitness components (e.g., size at birth, growth, age and size at maturity, number of offspring, rates of survival, and lifespan) trade off against each other. For instance, investments in offspring quantity trade off against offspring quality. Life histories are life course patterns of investments in fitness components that emerge from trade-offs and are often conceptualized as falling along a fast-slow continuum. Whereas mice follow a faster life history trajectory and reproduce early, produce many

offspring, and engage in little parenting, elephants follow a slower trajectory and reproduce relatively late, have few offspring, and parent more extensively.

As recently described by Richardson et al. (2018), life history theory has also been leveraged to explain differences within species in terms of genetic differences as well as developmental plasticity (i.e., differences in developmental trajectories due to early environmental conditions). Applied to humans, the logic of tradeoffs has been used to explain the co-occurrence of investments in traits and behaviors that seem to optimize fitness in harsh and unpredictable environments (e.g., earlier puberty and sexual debut, lesser parenting effort, as well as greater aggression, risk-taking, mating effort), as well as the opposite pattern of investments, which seems to optimize fitness given safe and predictable conditions (e.g., later puberty and sexual debut, greater parenting effort, and lesser aggression, risk-taking, and mating effort). Mirroring the fast-slow continuum between species, the former has been termed a faster life history strategy in human research and the latter a slower life history strategy (Figueredo et al. 2006). Research has confirmed that faster life history strategies reflect harsher and more unpredictable early environments (for a review, see Ellis et al. 2009), although it is not yet clear to what extent this is due to gene-environment correlation and/or causal effects of early environment that change developmental trajectories (Barbaro et al. 2017; Richardson et al. 2018).

Research suggests that internal working models mediate the development of faster or slower life histories in humans. In particular, unpredictability schemas (e.g., belief the world is chaotic and unpredictable; Hill et al. 1997; Ross and Hill 2002; De Baca et al. 2016), present time perspective (Chisholm 1999; Copping et al. 2014; Kruger et al. 2008), and shorter life expectancies (Chisholm et al. 2005) seem to translate harshness and unpredictability into faster trajectories. In light of evidence that (a) faster strategies seem mediated by a focus on short-term survival and reproduction, (b) psychoactive substances provide the experience that substances and related stimuli are of great and immediate biological

importance, and (c) the costs associated with severe use are often realized over a longer term, researchers suggested that faster life history strategists are likely more vulnerable to SUDs (Hill and Chow 2002; Lende and Smith 2002; Richardson and Hardesty 2012). Subsequently, studies confirmed that greater substance use frequency and severity reflects lower levels on a dimension subsuming somatic, parental, and community integrative effort, and higher levels on a dimension subsuming indicators of mating competition (e.g., risk-taking, aggression, delinquency, and greater numbers of sexual partners; Richardson et al. 2014, 2016, 2017a, b, c).

Finally, applications of life history theory to the development and maintenance of SUDs also predict a shift of resource allocation with age toward parenting and nurturing of relationships and away from reproductive and survival goals (Hill and Chow 2002; Durrant et al. 2009). Risk taking behavior, which could be advantageous in mating competition, is expected to peak during young adulthood and decrease with age as individuals mature, obtain resources/status, and develop greater concerns for family welfare and long-term health/survival (Durrant et al. 2009; Hill and Chow 2002). This appears to be the case with SUD, which peaks in young adulthood and then subsides thereafter (Park et al. 2006). Young adult men, relative to women and older men, also engage in the highest levels of risky drinking; from an evolutionary perspective, this has much to do with competition for mates, which is more salient for young men than it is for women or older men (Hill and Chow 2002; Park et al. 2006).

False Fitness Theory

Emotions evolved to serve an adaptive purpose (Al-Shawaf et al. 2015; Buss 2000). Even those emotions that are subjectively experienced as aversive and unwanted are necessary (Buss 2000; Nesse 1994). Anxiety and fear potentiate action tendencies directed at avoiding or escaping from threats; anger promotes aggressive actions that can ward off danger and facilitate competition

for mates; disgust and disgust-related emotions (i.e., guilt, shame, embarrassment) mitigate eating spoiled/toxic foods and repeating noxious behaviors that could result in expulsion from a social group, and jealousy may signal threats to sexual or emotional bonds (Al-Shawaf et al. 2015; Buss 2000). Moreover, emotions that tend to be more pleasant, such as happiness, joy, excitement, and love, likely evolved to motivate various goal pursuits and enhance social bonds, which can enhance longevity, survival, and reproduction (Al-Shawaf et al. 2015). Finally, all emotions serve an invaluable communicative function (Tracy et al. 2015). Given that emotions function to reinforce behaviors that promote survival, circumventing natural emotional responses through substances have a deleterious impact, including giving a false sense of fitness.

In modern society, where unrealistic expectations of success are ubiquitous and self-concept is easily diminished (Buss 2000), self-medication and happiness-seeking through substance use can impair the brain's ability to detect real successes or threats, which can impair adaptive behavior (St John-Smith et al. 2013; Panksepp et al. 2002). Through substance use, humans have learned to directly stimulate pleasure pathways and bypass the natural function of positive emotions, which are meant to signal a reproductive or survival benefit; by doing so, substance use seems to create a sense of fitness where one does not truly exist (Nesse 2002; Sullivan and Hagen 2002). Moreover, substance-induced euphoria signals pathological wanting, signaling to the brain that substance use deserves the utmost attention, even when other goals such as finding food, resting, or caring for a loved one are more important and require forethought and attention (Durrant et al. 2009; St John-Smith et al. 2013; Panksepp et al. 2002). The prominent position that substance use can assume in an individual's life may disrupt relationships, childcare responsibilities, health maintenance, and other important goal-directed behavior. For example, when substance use interferes with experiencing positive feelings and attachment toward a child, the child is more vulnerable to neglect and abuse. Moreover, substance use can override necessary, albeit

unpleasant, emotions like disgust that can reduce the likelihood of engaging in otherwise repugnant acts (e.g., using contaminated needles). In sum, the false fitness effects of substances may disrupt threat detection, learning, coping, self-regulation, and the goal-directed behavior necessary for effective functioning.

Neurobiological Perspective

In the ancestral environment, moderate dosing of psychoactive toxins would have allowed for optimal activation of reward-related brain systems that supported behaviors integral for survival. The same neural systems in a contemporary environment may serve to “prime” the modern brain for addictive behaviors within certain contexts. As already discussed, these may include environments where synthetic drugs with high potency are readily available (Mismatch Theory), where chaotic home environments elicit impulsive behavioral traits (Life History Theory), or where a decoupling of emotional systems from environmental threats and successes allow individuals to bypass normal information processing systems (False Fitness Theory). Notably, advances in both neuropsychological and comparative research can help to support these evolutionary theories of addiction.

Initial support for these enduring physiological changes is provided by comparative evidence, which shows that the mesolimbic dopaminergic reward and opioid and endocannabinoid systems have been preserved, both anatomically and functionally, across phyla. In particular, the role of dopamine in modulating motivational responses to natural rewards is highly conserved and still observed even in worms and flies, which evolved 1–2 billion years ago (Nestler 2005). Moreover, amphibians and bony fish possess a developed opioid system for the purposes of pain perception (Dreborg et al. 2008; Sneddon 2004; Stevens 2004). In humans, research demonstrates that the same mu receptor that mediates motivation for opioids and narcotics may have enhanced mammalian social bonding over the course of evolution (Panksepp et al. 2002). Finally, an ancient

endocannabinoid system signals important functions throughout vertebrates, such as feeding, learning, locomotor control (Elphick 2012), and male fertility (Fasano et al. 2009).

The complex coordination between these reward learning and regulatory brain systems (e.g., NAc, extended amygdala, VTA, PFC, lateral habenula) seems to be preserved across rodents and primates (Scaplen and Kaun 2016). They also play a proximal role in the transition from controlled to compulsive drug seeking in humans (Koob and Volkow 2010, 2016). For example, nearly all drug intoxication is accompanied by the release of dopamine and opioid peptides into the ventral striatum (Mitchell et al. 2012; Volkow et al. 2007; Koob 2015). This serves to elicit appetitive, positive affective emotions (Baldo and Kelley 2007; Burgdorf and Panksepp 2006), high incentive salience (Berridge and Robinson 1998) and to reinforce drug consumption via stimulus-response and conditioned learning processes (Delgado 2007; Daniel and Pollmann 2014). The transition over time of these corticolimbic circuits from prefrontal to striatal control over drug seeking characterizes the move from associative learning to habit formation in individuals with SUDs (Everitt and Robbins 2005, 2013) and is causally linked to the development of addiction (Giuliano et al. 2019; Everitt and Robbins 2016).

In our evolutionary past, habit formation would have been essential for animal and human life (Newlin and Strubler 2007). Interestingly, habit formation circuitry – a mesolimbic system with dopaminergic neurons ascending from the midbrain to a dorsal and ventral striatal complex – has been observed in nonmammalian vertebrates (Nesse and Berridge 1997). While there may be some functional variation within these systems across phyla, findings hold some support for the idea that habit formation circuitry may reflect a preserved system once critical for the development of flexible goal-oriented behaviors, including the acquisition of feeding patterns and foraging (Hodgson 2008; Newlin and Strubler 2007), within an unpredictable and chaotic landscape (Doebeli and Ispolatov 2013).

While the acquisition of survival-related habitual behavioral patterns may have necessitated a progressive transition from prefrontal to striatal control (Everitt and Robbins 2013), natural limitations within the ancestral environment (sparsity of drugs, less potency, positive reinforcement of legitimate fitness) were likely to have provided the regulatory parameters to render substance use adaptive (Saah 2005). In contrast, in our modern environment, thwarting natural selection processes can render these latent processes a liability. Hypofrontality in emotional and cognitive regulatory systems and sensitization of limbic circuits underlying conditioned responses often culminate in a loss of control over enhanced drug salience (Volkow and Boyle 2018).

Negative reinforcement processes are also triggered by the majority of drugs through acutely stimulating core stress system activity within the extended amygdala and habenula, via elevated release of hypothalamic CRF, HPA axis markers, NE, and dynorphin (Koob and Volkow 2016; Koob 2009; Wemm and Sinha 2019). This engagement of the stress systems modifies reward-related behavior through stimulation of mesencephalic dopaminergic transmission (Piazza and Le Moal 1997). Importantly, elevations in core stress system sensitivity and the persistent nature of an enhanced dysphoria and anxiety underlie the propensity for individuals to misuse many drugs of abuse including cocaine, alcohol, opioids, and nicotine (Fox and Sinha 2009; McKay 2011; Sinha 2008; Fox et al. 2007; Cosci et al. 2011). Moreover, activation of the stress response also represents an evolutionarily conserved neural response, with a substantial survival value, including initiating fight or flight behavior in the face of predators, faster reaction time, and increased cognitive acuity from sympathetic arousal (Nesse et al. 2007).

The selective advantage afforded by the stress response is also evidenced by the fact that despite the high health-related costs associated with chronic stress reactivity, it has been preserved by natural selection. This is further exemplified by the fact that all vertebrates produce corticosterone (Raff 2016), peptide sequences similar to human ACTH are observed across phyla (Nesse and Young 2000), and the upregulation of basal stress

hormones has been shown to be a phylogenetically common response to stressful circumstances (Adamo and Baker 2011), and one that is also linked to attenuated predation (Adamo et al. 2013). In view of this, the ability of many psychoactive agents to increase energy and attentional acuity, by activating HPA and autonomic stress systems (Tsigos et al. 2016), may again have represented immense survival value in our ancestors.

In a contemporary society, persistent activation of these evolved circuits may culminate in a dampened motivation for nondrug rewards, an enhanced dysphoric emotional state, and an overriding of prefrontal control networks. In short, the human brain may be “primed” for addiction (Durrant et al. 2009; Lewis 2015). Whereas our ancient brain circuitry can predispose modern humans to addiction, it does so by permitting the flexibility to develop goal-related behaviors. Dysregulations within these systems reflect neuroplastic adaptations that, in the case of addiction, are associated with highly maladaptive behaviors. In other words, addiction is an extreme consequence of a normal functioning brain. An evolutionary psychobiological approach to addiction may provide a picture of a disorder rather than a disease (Henden and Gjelsvik 2017) somewhat akin to a “biological hangover.” Conceptualizing addiction in this way may serve to bridge the divide between conceptualizing addiction as an incurable condition or one that can be overcome by a sense of agency and personal responsibility.

Conclusion

Accounts of human substance use from an evolutionary psychology perspective are integrated with neurobiological findings to understand SUDs as a modern societal ill. Cognitions and behaviors associated with a fast life history maintain vulnerability for SUDs in a modern world that does not reward such traits. In addition, because the human brain did not evolve to process widely available, frequently used, and highly potent substances, an evolutionary mismatch may contribute to the development and maintenance of substance use disorders. Moreover, emotional systems that

evolved to signal threats and to actuate adaptive, goal-directed behavior are out of step with SUDs that signal fitness where fitness does not exist. In an age of sophisticated drug manufacturing, including rapidly advancing synthetic substances, the SUD problem is expected to persist.

While genetic variability has certainly contributed to vulnerabilities that facilitate maladaptive drug seeking, Hill and Newlin (2002, p. 378) caution against using evolutionary theory to support ideas of a “genetic determinism” where it may be wrongly presumed that experience does not influence behavior. Indeed, it is well known that learning is a primary component of behavior and that experience influences gene expression including whether genes are expressed at all (National Scientific Council on the Developing Child 2010). As such, the continued development of cognitive and behavioral therapies that strengthen brain areas involved with self-control combined with policy focused on reducing availability of substances and preventing early life adversities may help to curb the SUD problem. Moreover, a focus on enhancing dimensions of slow life history and curbing those indicative of a fast life history may help to prevent and treat SUDs (Richardson et al. 2019).

An evolutionary approach may also help to reduce stigma and encourage individuals with SUDs to seek treatment. Therapists may benefit from acknowledging that the brain is wired for habit formation and that habit patterns are commonly beneficial and at times necessary for survival. At the same time, therapists can communicate that, even though ingestion of toxins in very low doses may have at one time had fitness benefits, modern developments including the development and wide availability of potent substances that create a false sense of fitness have warped any benefit of this habit system and have, in fact, caused major brain and behavioral disruptions.

Synonyms

Self-destruction; To kill yourself

Definition

Suicide is defined as an intentional, self-inflicted death.

Introduction

Suicide is a social phenomenon that can be described as an issue of public health. According to the World Health Organization (WHO 2019a), suicide kills over 800 thousand people worldwide, which translates to one death every 40 s. In 2016, suicide was marked as the 18th leading cause of death in the world, accounting for 1.4% of all deaths. Among those between 15 and 29 years of age, it is the principal cause of death. Other statistics reveal diverse aspects of suicide. For example, suicide is more prevalent among males who usually use more lethal methods. However, women engage in more suicide attempts than do men.

WHO's mortality database allows a broad vision of deaths reported by each country as a suicide. Considering the last reported number, provided between 2014 and 2016, the largest amount of deaths by suicide is found in the United States of America, with over 44 thousand deaths. Japan comes in second, with more than 23 thousand deaths, and Brazil comes next, with more

than 11 thousand deaths by suicide. In addition, France, Mexico, and the United Kingdom reported over 8, 6, and 4 thousand deaths by suicide, respectively (WHO 2019b).

Despite the statistics, the answer to the big question remains a debate in all related science and research fields: why do people want to take their own lives? Aiming to answer this question, many theorists and science fields have attempted to explain suicide in a range of different perspectives. Currently, the theme "suicide" is investigated from diverse angles in suicidology – the field of science dedicated to studying and investigating suicide and suicide-related thoughts and behaviors.

O'Connor and Nock (2014) argue that the most grounded research into suicide began in the 1950s and grew substantially in the last 25 years. The authors list the most prominent contemporary theories on suicide, beginning with the cubic model of suicide by Shneidman (1985), including models as the interpersonal-psychological model of suicide by Joiner (2005) and the cognitive model of suicidal behavior by Wenzel and Beck (2008), and end with ideation-for-action theories – a group of more recent suicide theories (for a brief review of the mentioned theories, see O'Connor and Nock 2014). Another group of recent theories deserves to be emphasized, given that they promise to make a difference toward a better understanding of suicide. These theories are united in what literature has been calling the "Ideation to Action Framework" (Klonsky et al. 2018). Basically, it includes four main propositions so far: Interpersonal Theory (IPT), Integrated Motivational Volitional Model (IMV), Three-Step Theory (3ST), and Fluid Vulnerability Theory (FVT). The major difference between these theories and the ones proposed before them is that these theories understand suicide as two different phenomena instead of just one. Specifically, they divide the concept of suicide into (a) the development of suicidal ideation and (b) the progression from suicide desire to attempts (Klonsky et al. 2018).

Although the Ideation to Action Framework is a new way of conceptualizing suicide, it is already backed up by scientific evidence. According to Klonsky et al. (2018), evidence gathered so far allows researchers to draw some important

conclusions. For example, attempters are distinguished from ideators by their capability for suicide, and pain and hopelessness motivate suicidal desire more than other factors. Nonetheless, as outlined by Aubin et al. (2013), suicide can be understood from the lenses of diverse perspectives. For example, biological theories suggest that suicidal behavior occurs from a combination of biological vulnerability and a psychosocial stressor. Systemic or developmental theories propose that disturbed social forces and family systems are crucial for understanding suicide. Cognitive theories combine a more extensive range of theories and important correlated constructs. For example, cognitive-behavioral theories emphasize the roles of hopelessness, the emotional dysregulation, and the perception of entrapment, among other cognitions (Aubin et al. 2013).

This entry aims to sum up how suicide has been studied from an evolutionary perspective. Specifically, we begin by reviewing the current position of researchers investigating suicide in nonhuman species. After that, we discuss how is it possible for behavior such as killing yourself to be selected for and maintained in humans. It is important to highlight that there we do not aim to cease the debate regarding this theme or present all the existent perspectives in the literature, but instead highlight the complexity of suicide.

Suicide from an Evolutionary Perspective

Through an evolutionary lens, suicide does not appear to make sense at first glance. If this was a romantic novel, suicide would be described as the point where “the plot thickens,” given that the most natural and primal urge of humans is disregarded: the instinct of survival and reproduction. Suicide in this field can be described as a choice to zero out your fitness. Even so, it is a topic with valid theoretical hypotheses behind it. Mainly, evolutionary theorists stress that the goal of evolutionary psychology is to provide clues on ultimate causation and thus explore why the phenomenon exists (Aubin et al. 2013).

There is still a lot of debate toward the premise that suicide can be found in both humans and non-human animals, the major goal being to answer: can nonhuman species commit suicide? Peña-Guzmán (2017) argued positively on this issue; Soper and Shackelford (2018) argued in response that when it comes to other species, suicide is not found due to cognitive limitations of nonhuman species and evolutionary mechanisms that would have already eliminated any suicide genes – had they ever existed. Soper and Shackelford (2018) contend that there is not enough evidence to support suicide in nonhumans and the behaviors described by some as suicide are, in fact, a result of risk-taking behaviors selected by the environment or a sacrifice of their soma in accordance to algorithms of inclusive fitness. In both cases, the main argument is that once the animal has ended its reproductive and protective roles, it has nothing to lose. Therefore, the fact that in some species members die by defending their colonies or in other species they die after their reproductive life is over would not, arguably, qualify as a suicide.

Despite this issue, suicide in humans is an undeniable phenomenon. Hence, in 2013, Aubin and colleagues outlined the main theoretical propositions regarding suicide from an evolutionary perspective: the bargaining hypothesis, the altruistic suicide hypothesis, and the parasite manipulation hypothesis. The bargaining hypothesis posits that suicide attempts function as a gamble, with support by the fact that most attempts are nonfatal. According to this hypothesis, suicidal behavior is a cry for help to a community, which would act as a signal that if assistance or change is not provided in face of a conflict, it will have evolutionarily cost for the community. The gamble consists of measuring the expression of need, because the false exaggeration of need often results in no help, as the honest signal of need usually motivates people with pre-existing interests to help in order to avoid a fatal outcome.

The altruistic suicide hypothesis is based on a mathematical formula developed by De Catanzaro (1991). It affirms that it is possible to assess the residual capacity of an individual to influence his inclusive fitness. In other words, this measure is believed to predict the degree to which self-

preservation is optimally expressed. Regarding suicide, it has been shown that the association of burdensomeness toward kin and low residual reproductive potential can lead to negative values. Basically, suicide may be seen as an altruistic self-destructive (i.e., suicide for the good of the group) behavior when a person is of negative value, according to this hypothesis. Support for this position has been found in a wide variety of organisms, such as unicellular organisms, parasites, and possible in mammals (Aubin et al. 2013; Taylor-Brown and Hurd 2013). In nonhuman animals, the self-sacrifice persists because of its positive impact on the fitness of the colony's reproductive individuals. For example, suicidal defense behaviors can be a consequence of engaging in combat to defend the colony, as a way to rid the nest of an enemy, and even as an altruistic self-removal by sick or contaminated individuals to (presumably) diminish the risk of contamination in the nest. Under this view, human suicide can also be an act of altruism in cases that the reproductive value of an individual is low. In fact, social isolation and perceived burdensomeness toward family has been correlated with suicidal ideation (Shorter and Rueppell 2012). Historically, suicide in old cultures (e.g., Inuits) has been considered altruistic in cases where someone was old or ill and would kill themselves or ask to be killed in order to not be a burden in times of poor hunting. At an individual level, if someone perceives themselves to be a burden, the act of killing themselves might be motivated by the same altruistic principle.

And lastly, the parasite manipulation hypothesis is grounded in literature on modifications induced by a parasite on host behavior. Like in the animal field, humans can also be infected with parasites that have an ability to modify human behavior, and this hypothesis suggests that such parasitic behavioral modifications are what cause suicide. Nonetheless, this is just a hypothetical scenario. For example, Aubin et al. (2013) argue that the *T. gondii* parasite can present a possible explanation for suicide. *T. gondii* is an intracellular protozoan that can infect all mammals, including humans, and its infection in humans was found to be related to mental disorders and behavioral alterations (often subtle), like altered

personality profiles (reviewed by Aubin et al. 2013). This evidence contributes to the assumption that suicide may be caused or increased by such parasite behavioral manipulations.

The Study of Clusters in Suicidal Behavior

“Suicide clusters” refer to multiple suicidal behaviors or completed suicides that occur within a relatively short time frame and/or within a specific geographical area (e.g., Zenere 2009), although the definition of a cluster varies widely with regard to the number of deaths and the temporal proximity in which they must occur. The study of suicide clusters covers suicide's apparent contagion characteristics, specifically studies about the “Werther effect” (i.e., the increase in suicides after a widely publicized suicide) and the different types of clusters known in the literature (for a review, see Haw et al. 2013). As the understanding of suicide clusters advances, evolutionary psychology also contributes to this field with the notion of suicide copycats. This concept refers to the tendency that humans copy each other, especially those who are seen as persons of success, and this tendency may lead to the spread of biologically maladaptive traits like suicide (Mesoudi 2018).

In short, two main types of clusters are widely studied: mass clusters, which are a phenomenon that occurs in a restricted period of time after the media disclosure of real or fictional suicides, and point clusters, which are characterized by a high number of suicides occurring in a small geographical area or institution over a relatively short period of time. More recently, another type of cluster is mentioned: echo clusters. Echo clusters are defined as geographic locations that gather many suicides over long periods of time, such as the Golden Gate Bridge (Haw et al. 2013).

Risk and Protective Factors of Suicide

It is very common for researchers in suicidology to investigate risk factors related to suicidal

behaviors. Protective factors, although less common, are also investigated by some researchers. For example, using principles from research into suicide clusters (e.g., Brent et al. 1989; Haw 1994), it was found common for cluster participants to have a history of suicidal ideation and a previous diagnosis of a mental disorder. Proximity to the original victim in the cluster also predicted a more rapid onset of suicide symptoms (Gould et al. 1989). In this way, the study of clusters contributes to the investigation of the contagion of the phenomenon, endorsing the importance of variables that can be configured as possible risk and protective factors.

Usually, the published material on risk and protective factors are concerned in identifying what figures as a risk/protective factor in different populations or specific phenomena. For instance, Gvion and Levi-Belz (2018) conducted a systematic review of the psychological risk factors for serious suicide attempts and identified that interpersonal problems, impulsivity, and aggression seem to facilitate the occurrence of serious suicide attempts. However, risk factors can also be explained by considering evolutionary psychology's propositions, as noted by Aubin et al. (2013). What is called a "risk factor" can also be understood as nonadaptive by-products of evolved mechanisms that malfunction. For example, mental disorders are often present in suicide cases, and evolution has shown that negative emotional states can be useful in accomplishing a diversity of goals, such as expressing a need for help or signaling the act of yielding in a hierarchy conflict. Even so, it can also lead to the inhibition of certain behaviors that can protect the organism, such as the fact that sadness, pessimism, and lack of motivation can inhibit actions in the absence of a practical plan or in dangerous or futile challenges to dominant figures.

Similarly, to those risk factors used as examples, evolutionary psychology has tackled a great number of risk factors described by literature and joined it with its functional explanation. This includes specific behaviors associated with depression and suicide, such as crying (which elicits empathy and may increase social support), and specific markers, such as negative cognitive bias (which is likely to result in an overvaluation of perceived

burdensomeness and increase the risk of altruistic suicidal behavior; Aubin et al. 2013). Even though risk factors offer a useful way to work within suicidology, theories about the phenomenon of suicide are also abundant in today's literature.

Conclusion

Suicide is a worldly health problem. Different perspectives of studying and trying to explain this human behavior, collectively, converge within suicidology. Cognitive theories have been the focus of research fields and interventions; however, an evolutionary perspective may provide a deeper understanding of the adaptive significance of suicide and contribute to the creation of prevention strategies. For example, considering the promising theories within the Ideation to Action Framework, reduction of perceived burdensomeness and hopelessness in the mating arena might represent an effective prevention strategy.

Introduction

Suicidal behavior is a universal human phenomenon. Globally, suicide accounts for more deaths than all wars and homicides combined (Lozano et al. 2013). However, evolutionary theorists have for many decades largely overlooked suicidal behavior reasonably regarding the act as pathological or a byproduct of other mechanisms. However, given the universality and commonality of suicidal behavior, self-destructive behavior in all its forms is worth investigating from an evolutionary perspective. Two promising evolutionary theories of suicidal behavior are the inclusive fitness model (1981, 1984, 1991, 1995) and the bargaining model (Syme et al. 2016).

The Inclusive Fitness Model

The inclusive fitness model of suicide, developed by psychologist Denys deCatanzaro, takes an adaptationist view suicide wherein willful self-destruction is a means of increasing one's inclusive fitness. According to the model, suicide will be adaptive when an individual has low reproductive potential and is imposing net costs of genetic kin, such as in the case of a debilitating illness (1981, 1984, 1991, 1995).

There is evidence for the inclusive fitness of model from different areas of research. For example, there are examples of self-sacrifice for the benefit of genetically related individuals in non-human species such as sterile castes of the order Hymenoptera for the purpose of colony defense (Preti 2007). In *E. coli*, self-sacrifice appears to limit the transmission of a bacteriophage to even distantly related organisms (Refardt et al. 2013).

There is some evidence that low reproductive potential and burdensomeness map on to suicide. Cross-national statistics on suicide completions in the West demonstrate that the risk of suicide death increases with age as reproductive potential decreases and as the potential of being a burden on kin due to illness increases (Shah 2007). Moreover, suicidal ideation often corresponds to the perception of being “better off dead” or making others “better off.” There is an association

between chronic pain, a possible cue of burdensomeness, and suicide (e.g., Ratcliffe et al. 2008).

Investigators have tested the inclusive fitness model directly. In a study conducted deCatanzaro (1995), self-reports of low reproductive prospects and low valuations of one's worth to their family correlated with suicidal ideation. In a test of the inclusive fitness model against 53 distinct geographically diverse cultures in the ethnographic record, Syme et al. (2016) found that evidence for deCatanzaro's inclusive fitness model increased as a function of latitude. Thus, there was greater evidence for inclusive fitness model suicides in resource-scarce environments such as the Arctic where the provisioning of nonreproductive and infirm kin can be costly. Finally, according to Brown et al. (2009), low measures of health and low satisfaction in romantic relationships were associated self-destructive motivation among college students. In this same study, the researchers also found an inverse relationship between maternal age and self-destructive motivation, indicating that the reproductive value of kin might moderate the desire for suicide.

Clinical psychologist Thomas Joiner developed a model deemed the interpersonal theory of suicide that was partially informed by deCatanzaro's work. Joiner and his colleagues contend that a lack of belongingness, a sense of burdensomeness, and an acquired ability for suicide (e.g., self-harm, violence) lead to suicide completions (Van Orden et al. 2010). This model, while potentially illuminating in the clinical context, does not provide a complete evolutionary explanation for suicidal behavior and lacks appropriate modeling that demonstrates how such traits could be maintained by natural selection.

Kin directed suicide might explain some but not all cases of suicidal behavior. deCatanzaro (1995) noted that novel technology, such as guns and cars, could cause suicide death even in individuals with otherwise high reproductive potential and low burdensomeness. In such cases, the evolved human mind fails to take into its calculations the high lethality of these technologies. Furthermore, the vast majority of suicidal behavior is, in fact, nonlethal. For example, among US

females, there are about 400 suicide attempts for every one suicide completion (see Syme et al. 2016). Thus, much suicidal behavior occurs among young, healthy individuals who are not burdening their kin.

The Bargaining Model

The bargaining model is game theoretic model of suicidal behavior that was developed by anthropologist Edward Hagen and was originally applied to depression (Hagen 1999, 2003). This model of suicidal behavior sees nonlethal suicide attempt as a costly signal of need that will occur in the face of a severe fitness threat and a conflict of interest between the victim and social partners who are otherwise interested in his or her fitness. The suicide victim will likely have high reproductive potential such that the loss of this individual within the kin network represents a loss of fitness. Suicidal behavior is therefore a means for the powerless to strike back at powerful others in the face of injustice and conflict.

The employment of suicidal gestures as a means for relatively powerless individuals to protest or seek revenge on others is well documented in the ethnographic record. Among the Trobrianders, for example, suicide acted as a protest when one was falsely accused of a wrongdoing (Malinowski 1926). The Huron-Iroquois similarly regarded suicide as means to harm others in the event of a dispute (Fenton 1941). Women in regions as distinct as Afghanistan and Papua New Guinea engage in suicidal behavior (SB) to attack oppressive males, typically fathers and husbands who mistreat them (Billaud 2012; Johnson 1981). Among the Chuukese, suicide also communicates anger and dysphoria and calls attention to social tension (Hezel 1987). These accounts bear a similarity to "cry for help" models developed by psychiatrists and psychologists in the mid-twentieth century such as Stengel (1952) as well as Farberow and Shneidman (1961). However, despite far-reaching empirical support for these models, terminologies such as "cry for help" have fallen out of favor in professional fears due to valid concerns that such framing trivializes

nonlethal suicide attempts. On the other hand, the bargaining model, far from trivializing suicidal behavior, in fact, argues that it is an honest signal of social need.

Syme et al. (2016) tested the bargaining model against 53 cultures in the ethnographic record. In sum, suicidal behavior by young, healthy individuals in the face of a social conflict and severe fitness threat was common across cultural regions, though more research is necessary to confirm if this model is indeed operating in some instances. If the bargaining model is true, then this has critical implications for treating suicidal patients. Specifically, this would suggest that patients would be best treated socially rather than pharmacologically.

Conclusion

Multiple evolutionary models of suicidal behavior hold up against tests of these theories in different contexts. Suicidal behavior is, thus, a highly heterogeneous phenomenon. More research is needed, however, to confirm these theories. The inclusive fitness model might operate in resource-scarce environments that limit the ability of others to provision infirm family members. Features of the bargaining model, on the other hand, are common across diverse cultures. Social conflict, powerlessness, and fitness threats frequently precede suicidal gestures in a range of social and environmental contexts. The characteristics of suicide victims in each model are distinct. Whereas the inclusive fitness model will tend to apply to older individuals, the bargaining model concerns younger individuals with high reproductive potential. Thus, rather than competing, these two models might coexist.

[Inclusive fitness model of suicide](#)

Definition

The inclusive fitness model of suicide asserts that willful self-sacrifice can be maintained by natural selection when one has low reproductive potential and imposes costs on genetic kin.

Introduction

The inclusive fitness model of suicide, developed by psychologist Denys deCatanzaro, takes an adaptationist view of suicide wherein willful self-destruction is a means of increasing one's inclusive fitness. According to the model, suicide will be adaptive when an individual has low reproductive potential and is imposing net costs of genetic kin, such as in the case of a debilitating

illness (1981, 1984, 1991, 1995). Focusing on suicide completion, this model is contrasted with other evolutionary models of suicidal behavior that concern nonlethal suicide attempts (e.g., the bargaining model, see Syme et al. 2016).

Research on Suicide as Kin-directed Altruism

There is evidence for the inclusive fitness of model from different areas of research. For example, there are examples of self-sacrifice for the benefit of genetically related individuals in non-human species such as sterile castes of the order Hymenoptera for the purpose of colony defense (Preti 2007). In *E. coli*, self-sacrifice appears to limit the transmission of a bacteriophage to even distantly related organisms (Refardt et al. 2013).

There is some evidence that low reproductive potential and burdensomeness map on to suicide. Cross-national statistics on suicide completions in the West demonstrate that the risk of suicide death increases with age as reproductive potential decreases and as the potential of being a burden on kin due to illness increases (Shah 2007). Moreover, suicidal ideation often corresponds to the perception of being “better off dead” or making others “better off.” There is an association between chronic pain, a possible cue of burdensomeness, and suicide (e.g., Ratcliffe et al. 2008).

Investigators have tested the inclusive fitness model directly. In a study conducted deCatanzaro (1995), self-reports of low reproductive prospects and low valuations of one's worth to their family correlated with suicidal ideation. In a test of the inclusive fitness model against 53 distinct geographically diverse cultures in the ethnographic record, Syme et al. (2016) found that evidence for deCatanzaro's inclusive fitness model increased as a function of latitude. Thus, there was greater evidence for inclusive fitness model suicides in resource-scarce environments such as the Arctic where the provisioning of non-reproductive and infirm kin can be costly. Finally, according to Brown et al. (2009), low measures of health and low satisfaction in romantic relationships were associated self-destructive motivation among college students. In this same study, the

researchers also found an inverse relationship between maternal age and self-destructive motivation, indicating that the reproductive value of kin might moderate the desire for suicide.

Kin directed altruism as a motivation for suicide might explain some but not all cases of suicidal behavior. deCatanzaro (1995) noted that novel technology, such as guns and cars, could cause suicide death even in individuals with otherwise high reproductive potential and low burdensomeness. In such cases, the evolved human mind fails to take into its calculations the high lethality of these technologies. Furthermore, the vast majority of suicidal behavior is, in fact, nonlethal. For example, among US females, there are about 400 suicide attempts for every one suicide completion (see Syme et al. 2016). Thus, much suicidal behavior occurs among young, healthy individuals who are not burdening their kin.

Conclusion

Though there is considerable support for the inclusive fitness model of suicide, not all cases of suicidal behavior correspond to the necessary conditions of the model. Suicidal behaviors are heterogeneous phenomena that might not fit under one evolutionary model.

Definition

Suicide terrorism, which is usually tied to a non-state organization, is the act of sacrificing one's life in an effort to harm, damage, or destroy members of an out-group, for political and social objectives.

Introduction

Although suicide terrorism is not a particularly modern phenomenon, research on its underlying causes flourished since the September 11 terrorist attacks. Some scholars have turned to the principles of evolutionary psychology in an attempt to shed light on suicide terrorism. Before delving into the topic of suicide terrorism from an evolutionary perspective, we briefly define some of the relevant terms in evolutionary psychology and examine the phenomenon of terrorism more generally. Following this, a brief summary of some of the psychological factors implicated in terrorism will be provided. Finally, three of the dominant explanations for suicide terrorism from an evolutionary psychological perspective will be presented, as well as an integration of research from the fields of psychology and evolutionary psychology.

Relevant Concepts in Evolutionary Psychology

Before examining terrorism and suicide terrorism from an evolutionary psychological perspective, a review some of the relevant key concepts in evolutionary psychology is warranted. Central to the concept of evolution is the notion that organisms have evolved by way of natural selection. During our evolutionary history, humans have ultimately differed in their ability to survive and reproduce. Certain factors in our ancestral environment – known as the *environment of evolutionary adaptiveness* – have led to the selection of *psychological mechanisms* which produce certain patterns of behavior (Cosmides and Tooby 1987). These evolved mechanisms can be seen as psychological adaptations, in the form of information-processing circuits in our brains which produce

specific behavioral patterns (Cosmides and Tooby 1987). Importantly, these psychological mechanisms evolved because they solved specific adaptive problems related to survival and reproduction. In other words, psychological mechanisms which facilitated greater chance of survival and reproductive success in the given environment were selected for, whereas those which did not increase the chance of survival and reproductive success decreased or were eliminated from the gene pool. It follows that these evolved psychological mechanisms generally lead humans to behave in ways which are adaptive, such as avoiding harm and attracting mates in order to produce healthy offspring. However, behaviors do not always evolve because they are adaptive; they can also evolve as a *by-product* of an adaptive mechanism. A by-product is a trait that evolved not because it was selectively advantageous but because it was linked to another trait which was reproductively advantageous. In other words, certain behaviors might be triggered because they “tap into” adaptive psychological mechanisms.

During human evolution, individuals have also engaged in helping behavior that appears to have no direct adaptive benefit for themselves and in many cases can be costly or dangerous to the individual. Within the field of evolutionary psychology, this phenomenon is referred to as *altruism*. Altruistic behavior is characterized by self-sacrificial, costly, helping behavior in the absence of apparent external rewards. However, it is widely debated whether prosocial behaviors can ever be truly selfless or altruistic. Moreover, scholars have argued that in many cases, individuals engage in helping behaviors with the expectation that the favor will be directly reciprocated by the beneficiary of the favor (*direct reciprocity*) or that they will be helped or rewarded indirectly by other individuals (*indirect reciprocity*) (Trivers 1971), due to an enhanced reputation for helping. Others have proposed that in general, individuals act in order to maximize the fitness of their kin. *Kin selection theory* arose from Hamilton's (1964) model of inclusive fitness, where he proposed that an individual engages in altruistic behavior if the benefits of the behavior

for genetic relatives outweigh the costs to the individual. In mathematical terms, Hamilton proposed that natural selection will favor the gene for altruism whenever $r \times b > c$, where r = the degree of genetic relatedness, c = costs, and b = benefits.

The aforementioned models of altruism will be discussed again later in this entry, when assessing how these models might relate to the phenomenon of suicide terrorism. It is important to note that these models, which are based on an evolutionary psychological perspective, focus on the fitness consequences of behavior, also known as *ultimate* explanations of behavior (Scott-Phillips et al. 2011). In contrast, *proximate* explanations of behavior refer to more direct causal triggers of a behavior (Scott-Phillips et al. 2011). While it is virtually impossible to directly test evolutionary models of behavior empirically, and even more difficult to do so in the context of terrorism and suicide terrorism, one can examine whether evolutionary explanations converge with widely accepted psychological explanations for this type of behavior. Thus, in the sections that follow, a brief overview of terrorism and suicide terrorism and their modern-day manifestations, and some of the psychological factors implicated in terrorism behavior more generally, will be outlined.

These factors can be seen as proximate explanations, which can later be examined in relation to their fitness benefits (i.e., ultimate explanations). Subsequently, we will provide perspectives on these behaviors from the field of evolutionary psychology and examine how current research evidence converges with different evolutionary psychological models.

Terrorism and Suicide Terrorism: A Brief Summary

The definition of terrorism has been the subject of much of debate, and leading scholars in the field of terrorism have yet to agree upon a specific definition. One common theme in ongoing debates about what constitutes terrorism centers on whether the definition should include acts of violence perpetrated by state actors (i.e., state-sponsored terrorism). Because the majority of research and theorizing about the underlying causes of terrorism tend to focus on the violence

perpetrated by non-state actors/organizations, this entry will largely focus on this subcategory of terrorism.

Thus, terrorism can be defined as the “symbolic use of violence by nonstate actors with social and political (hence not purely criminal) objectives intended to intimidate, frighten, or coerce a wider audience than the direct (instrumental) targets of the attack” (Kruglanski and Fishman 2009, p3). Historically, many terrorist organizations have emerged in response to ongoing ethnic/religious conflicts (sometimes with regard to claims to land) and often involving the oppression of specific minority groups. Although there are instances of “lone actor terrorism,” the majority of terrorist attacks are connected to terrorist organizations, which can be roughly categorized as Jihadist, ethno-nationalist/separatist, right-wing, left-wing and anarchist, and single-issue terrorism (e.g., anti-abortion terrorists).

Suicide terrorism is a more extreme extension of this tactic whereby the perpetrators of the attack are aware that they will lose their life as a direct result of harming or destroying the target. Suicide attacks are not a particularly new phenomenon and have long been considered a “weapon of the weak,” often employed when previously employed tactics have failed to achieve their goals. For example, suicide attacks were adopted by Japan during World War II, in the form of the kamikaze attacks, whereby pilots crashed explosive missiles into Allied naval vessels (Orbell and Morikawa 2011). Although these kamikaze attacks would be classified as an instance of a state-sponsored suicide terrorist mission, the majority of suicide attacks in modern times are perpetrated by non-state terrorist organizations. Notably, the rise of religious fundamentalist terrorism in the last several decades has coincided with the increased use of suicide terrorism as a strategy employed by Jihadist organizations/Islamist militant groups including Al-Qaeda, Boko Haram, ISIS, Hezbollah, and Palestinian Islamic Jihad. In 2017, suicide bombings occurred in 27 different countries and were tied to 37 different Islamist militant groups (Global Extremism Monitor 2017). However, suicide terrorism has

also been adopted by nonreligious groups such as the Liberation Tigers of Tamil Eelam (LTTE) (Moghadam 2006).

Although the actual act of suicide terrorism can take many different forms, the most common form is suicide bombing whereby the “agent” of suicide terrorism agrees to be strapped to an explosive device (or drive a vehicle carrying explosive devices), which is subsequently detonated once the agent has reached its target or target population. This particular type of suicide terrorism gained popularity among Islamist militant groups in Palestine (i.e., Hamas) and Lebanon (i.e., Hezbollah) in their violent conflicts with the state of Israel. Two of the most high-profile suicide terrorist attacks against the West were the September 11 attacks and the London bombings in 2005. While the terrorist organization Al-Qaeda was responsible for the September 11 attacks, it still remains unclear whether the men behind the London bombings had “self-radicalized” or were in fact tied to terrorist organizations. Most recently, the United States is witnessing a spate of what some consider white nationalist terrorism, typically perpetrated by lone male actors who have been radicalized on Internet message boards and other websites. The section which follows will examine some of the key theories and findings from the field of psychology, providing several explanations regarding the psychological underpinnings of suicide terrorism and terrorism more generally.

Psychological Perspectives on Terrorism and Suicide Terrorism

Despite the general consensus that the field of terrorism studies would benefit from an enhanced understanding of the psychology behind terrorism, the literature on terrorism from a psychological perspective has been subject to much critique. For obvious practical and ethical reason including the difficulties and dangers in gaining access to terrorist organizations or former terrorists and the inherent difficulties in planning prospective studies, there has been a lack of theory-driven empirical research. Moreover, the majority of research focusing on the association between psychology and terrorism has been characterized by theorizing

or speculation based on anecdotal observations (see Victoroff 2005 for a review).

One line of psychological research has focused on potential individual factors that may characterize terrorists. Early work on the psychology of terrorists was dominated by the preconception of the “terrorist as mentally ill.” However, in recent years, terrorism scholars generally agree that individuals involved in group-based terrorism are not mentally ill but “ordinary and unremarkable in psychological terms” (Silke 2008, p 118). Indeed, some scholars have suggested that there is no clear relationship between involvement in terrorism and psychopathology or personality traits (i.e., Horgan 2003). However, recently, a growing body of evidence suggests that a subjective sense of humiliation – which appears to underlie motivations to act out of revenge – is common among individuals who have been involved in group-based terrorism (Silke 2008).

Kruglanski and Fishman (2009) have proposed that terrorists – and suicide bombers in particular – seek to gain personal significance, which can be prompted by the loss of significance. This loss of significance can be attributed to feelings of humiliation, feelings of discrimination, or feelings of disenfranchisement. According to this theory, opportunities for significance gain may become apparent when one’s group experiences defeat or humiliation at the hands of an enemy (Kruglanski and Fishman 2009). Thus, what could originally be conceived of as an individual motivating factor is also tied to the psychology of belonging to a group. Specifically, an individual’s feelings of humiliation and motivations for revenge (or the quest for significance) are in many cases tied to the feeling that one’s social group has been treated unjustly (see Silke 2008). Notably, among Muslim diaspora, feelings of group-based anger, group-based injustice, and group-based relative deprivation have been found to predict violent intentions to defend Muslims (Obaidi et al. 2019). Hence, individual differences in emotions appear to be one area in which individual-level factors are linked to group-level factors.

Given that terrorism is often linked to organizations that mobilize ethnic or religious identity, there is a general consensus that terrorism tends to

be a group-based phenomenon. As Kruglanski and Fishman (2009) point out, “membership in a terrorist group may expose individuals to a unique social reality that condones violence, removes the anticipatory anxiety and guilt restraining one from harming innocents, stemming from societal norms that prohibit such behaviors” (p 16). In social psychological terminology, terrorism can be conceptualized as a violent form of intergroup conflict or nonnormative collective action triggered by perceived injustices perpetrated against one’s group. This view is supported by anecdotal evidence in the form of the justifications given by the leaders of some of the world’s most high-profile terrorist attacks. For example, Osama bin Laden (the former leader of Al-Qaeda, who was behind the September 11 attacks) and Mohamed Sidiq Khan (orchestrator of the London bombings in 2005) both expressed a sense of injustice against Muslims around the world by the hands of the West and the need to avenge these injustices (BBC News 2005; The Guardian 2002).

Terrorism from an Evolutionary Psychological Perspective

As stated in the section above, feelings of humiliation and motivations to take revenge are two individual psychological factors which appear to be implicated in terrorist motivations. Both humiliation and revenge might in fact be evolutionarily adaptive. Revenge can be defined as “an aggressive act that is often justified by the pursuit of equity” (Stillwell et al. 2008). From an evolutionary perspective, revenge can be considered a form of retaliation to perceived transgressions from one or more individuals, which functions to reduce the likelihood that the transgressor (i.e., target of retaliation) will engage in the same injurious transgressions in the future, hence leading to fitness gains (Clutton-Brock and Parker 1995). It has also been proposed that readiness to retaliate against transgressors could be partly due to concerns about one’s social reputation, which is important in primate and human societies (Clutton-Brock and Parker 1995). Moreover, the construct of humiliation is arguably linked to one’s social standing. Humiliation can be defined as “the experience of some form of ridicule, scorn,

contempt, or other degrading treatment at the hands of others” (Klein 1991, p.94). In this way, humiliation and revenge might have operated in concert with one another in ancestral environments, such that perceived transgressions are subjectively experienced as feelings of humiliation, which might trigger a motivation for revenge (i.e., retaliation), in an effort to deter the transgressor from committing further transgressions, or due to reputational concerns. In many instances, these transgressions might have been perpetrated by members of other social groups or tribes. Thus, acts of revenge can be considered as prosocial or even altruistic, if the individual stands to suffer and their group stands to gain. Indeed, some known terrorists have described themselves as behaving altruistically, for the best interests of their group (Victoroff 2005).

A dominant perspective with its roots in evolutionary psychology holds that the tendency for costly cooperation benefiting members of one’s in-group (i.e., altruism), and spite and aggression towards members of other groups (i.e., out-group hostility, parochialism), might have evolved simultaneously, a term which has been more recently coined “parochial altruism” (Choi and Bowles 2007). While there are other perspectives regarding the origins of in-group cooperation (e.g., Brewer 2007), researchers making use of game theoretic analysis agent-based simulations provide some evidence that altruism and parochialism could have evolved jointly (Choi and Bowles 2007).

In order to identify who should reap the benefits of group membership (i.e., cooperativeness and altruism) or be subject to out-group hostility (i.e., parochialism), humans developed the ability to group humans into rigid social categories, such as “Us” versus “Them” (Zmigrod et al. 2019). Although such rigid social categorization occurs to varying degrees for all humans, some humans are more rigid in their categorizations. Recent research suggests that such rigid social categorization which may underlie parochial altruism could more broadly reflect the individual tendency for rigidity in classification of stimuli more generally (Zmigrod et al. 2019). Specifically, Zmigrod et al. (2019) found that

individuals who have a greater propensity towards rigid evaluations of stimuli are more willing to endorse ideological out-group violence and more willing to engage in self-sacrificial behavior in order to benefit their in-group (Zmigrod et al. 2019). While engagement in terrorist acts more generally could be considered a form of warfare or intergroup aggression and thus understood as a manifestation of parochial altruism, suicide terrorism needs to be examined as a phenomenon slightly distinct from non-suicide acts of terrorism. In many ways, suicide terrorism could be considered the ultimate form of altruism.

Suicide Terrorism as Altruism

Suicide terrorism, which involves laying down one's life for the sake of the organization and its goals, is considered the ultimate form of self-sacrifice. Such behavior is initially puzzling for both laypeople and evolutionary psychologists, since it appears to be maladaptive and at odds with the evolutionary instinct to survive. However, despite the destructive nature of suicide terrorism, many scholars have viewed it as a form of suicide terrorism to other forms of self-sacrificial helping behavior and examined whether suicide terrorism is a form of altruism (Liddle et al. 2011; Orbell and Morikawa 2011; Qirko 2009). Indeed, in Palestine, suicide bombers are referred to as a *shaheed* (martyr) and deemed heroes in their communities because they have sacrificed themselves to destroy their enemy. This concept of martyrdom and self-sacrifice is also prominent among the Tamil society in Sri Lanka, with members of the LTTE's suicide squad (the Black Tigers) honored and revered after death (Moghadam 2006). Because of this element of self-sacrifice in order to benefit their group/organization, several scholars have examined whether altruism could possibly shed light on the adaptive functions of suicide terrorism. Thus, scholars have attempted to apply models of altruism to the context of suicide terrorism, assessing the plausibility of these models by examining the available evidence surrounding the perpetrators of suicide terrorism and the terrorist organizations that lie behind these attacks.

Suicide Terrorism as Direct or Indirect Reciprocal Altruism

One of the most popular – and perhaps most straightforward – explanations for altruistic behavior more generally is that individuals are willing to engage in costly or self-sacrificial behavior to help nonkin (individuals they are not genetically related to), because they expect the favor to be directly or indirectly reciprocated (Trivers 1971).

Whereas direct reciprocity occurs when individuals help those who help them, indirect reciprocity occurs when individuals help those who help others, due to an enhanced reputation for helping. Some scholars have been quick to conclude that reciprocity – whether direct or indirect – is unlikely to be the primary motivator in suicide attacks, since one needs to remain alive in order to receive any subsequent help or rewards. Qirko (2009), for example, has suggested that a suicide attack leads to the ultimate loss for the agent of suicide terrorism, with no further opportunities for compensation of the costly act of suicide. However, Qirko and other scholars (i.e., Tullberg 2004) have also acknowledged the possibility that in the minds of the agents of suicide terrorism, an unspoken and “illusory” reciprocal contract is made with the terrorist organization. In evolutionary psychological terminology, suicide terrorism could therefore be understood in terms of indirect reciprocal altruism, contingent on the agents of suicide terrorism believing they will receive subsequent rewards as a direct result of their ultimate sacrifice for the cause.

Specifically, some terrorist organizations, notably Islamist militant organizations, refer to suicide terrorists as martyrs. Within these contexts, martyrs are assigned a special status. In fact, martyrs are promised great rewards in the afterlife. For example, it is reported that Hamas suicide bombers have been promised entry to paradise upon death, accompanied by many other rewards including access to dozens of virgins (Tullberg 2004). Support for the notion of this illusory reciprocal contract comes from research which has shown that Palestinian suicide bombers do not believe they are really dying when they undertake their suicide bombing mission (Kershner

2001). Further evidence for this illusory reciprocal contract is that one motivation shown to be important among Palestinian suicide bombers is the prospect of receiving rewards in the afterlife (Hafez 2006). The fact that many religions stress the existence of the afterlife is one reason why scholars have argued that religious belief is a predictor of suicide terrorism. Liddle et al. (2011) reason that without the belief in the afterlife, and the accompanying belief that one will receive rewards in the afterlife, potential suicide terrorists would be likely to judge the costs of suicide (i.e., death) as far too costly to engage in Liddle et al. (2011). However, the existence of secular (i.e., nonreligious) terrorist organizations, which employ suicide terrorism as a strategy, as the LTTE in Sri Lanka, would appear to contradict the reciprocal altruism account, as well as the supposed key role of religious belief in the existence of suicide terrorism. In other words, the fact that some perpetrators of suicide terrorism act on behalf of nonreligious organizations would imply that such individuals do not hold beliefs about the afterlife, suggesting that the account of an illusory reciprocal contract involving rewards in the afterlife is not valid. Although acknowledging the existence of nonreligious terror organizations, Liddle et al. (2011) argue that the existence of suicide terrorists tied to secular terrorist organizations does not rule out the notion that these suicide bombers believe (or believed in) life after death. Nevertheless, from an evolutionary psychological standpoint, other alternative explanations based on the evolutionary principles of kin selection appear to provide more plausible explanations for the existence of suicide terrorism.

Suicide Terrorism and Kin Selection

Although the act of taking one's life would initially appear to be maladaptive, it could be considered adaptive if one shifts the focus from the individual to the individual's genes. Hence, an alternative explanation rooted in evolutionary psychology is the notion that suicide terrorism is a form of *kin selection*. The act of kin selection occurs when an individual engages in a behavior which leads to benefits for their (genetic) relatives, even when this behavior is costly for the

individual in terms of survival and reproduction (Hamilton 1964). In this line of reasoning, the seemingly maladaptive behavior is adaptive because close relatives share many of the same genes, and by helping related kin to reproduce (by engaging in the altruistic behavior), individuals may increase the frequency of these shared altruistic genes in the next generation.

Applying the kin selection model, engagement in suicide terrorism missions might be adaptive because the family of the suicide terrorist could reap rewards after the individual dies. Several scholars have examined the possibility that individuals engage in suicide terrorism due to kin selection (i.e., Lankford 2015; Liddle et al. 2011; Qirko 2009). Some scholars even suggest that suicide terrorism might in fact be adapted (Liddle et al. 2011; Qirko 2009), since in many cases the relatives of suicide terrorists receive both tangible and intangible rewards. Given that Islam holds that martyrs are awarded a special status and referred to as heroes, relatives of suicide bombers are greatly honored by their community and receive monetary rewards from one or more organizations. For example, reports from several different sources have revealed that Hamas and Hezbollah compensate the family members of suicide bombers with lump-sum payments (Levitt 2005). Moreover, there are even funds which have been initiated, with the sole purpose of dealing out payments to family members of suicide bombers (Levitt 2005). The cost of dying which is the inevitable result of carrying out a suicide attack could technically be offset by the fitness benefits for the genetic relatives. In this line of thinking, several scholars have suggested that when suicide bombers willingly take their lives in order to destroy or harm the organization's targets, the benefits that family members subsequently receive after the attack could mean that this act increases the likelihood that their shared genes are passed onto future generations (Liddle et al. 2011).

An alternative application of the kin selection model to the context of suicide terrorism stems from the observation that terror organizations often recruit family members (usually brothers) or friends of pre-existing members. For example,

Sageman (2008) drew attention to the fact that 70% of individuals who joined Al-Qaeda joined with friends, with 20% joining with family. According to this line of thinking, suicide terrorists might not be sacrificing themselves for the collective good nor attempting to accrue benefits for their relatives. Rather, they might actually be attempting to protect their relatives or close friends from harm. However, an alternative evolutionary psychological explanation stemming from the kin selection model suggests that the phenomenon of suicide terrorism has evolved as a by-product of kin selection, namely, induced or fictive kinship.

Suicide Terrorism as Induced Altruism/Fictive Kinship

Given that the kin of suicide terrorists do not always accrue benefits for their genetic relatives, an alternative explanation – with its roots in kin selection theory – has been proposed. According to Qirko (2004), where genetic relatives of suicide terrorists do not stand to benefit as a direct result of the suicide attack, individuals can be induced to act altruistically in order to benefit the terrorist organization to which they belong (Qirko 2004). According to this view, the same psychological mechanisms which initially evolved to prompt individuals to help their genetic kin are “hijacked” (Qirko 2004). That is, terrorist organizations make use of *kin recognition cues* – cues which allow individuals to distinguish between kin and non-kin – such as physical proximity, phenotypical similarity, and reference to individuals in kin terms (Qirko 2004). In this line of thinking, manipulation of kinship recognition cues induces some individuals to sacrifice themselves for their organization, because members of the terrorist organization essentially become “fictive kin” (Qirko 2004).

Qirko (2004) hypothesized that when one examines terrorist organizations, the cues of physical proximity, phenotypic similarity, and use of kinship terms should be evident in organizational practices. Indeed, there are some contexts in which manipulation of these kinship recognition cues appears to have been adopted. In many cases,

new recruits to terrorist organizations are placed in small groups or cells which promote close physical proximity (Atran 2003). Recruits are also given a uniform in the form of new clothes and accessories and encouraged to wear these, hence increasing phenotypic similarity (Atran 2003). Furthermore, terrorist organizations appear to make use of kinship terms when referring to the organization or members of the organization. Sometimes the organization is referred to as the individual’s new “family,” with individuals within the same group or cell often described as “brothers” (Atran 2003).

Critique of the Evolutionary Psychological Explanations of Suicide Terrorism

Evolutionary psychological explanations of suicide terrorism have also been subject to critique. In particular, the kin selection explanation of suicide terrorism has been criticized on several grounds. For example, Lankford (2015) argues that intentional self-sacrifice is maladaptive and would not have been selected for. To support his argument, Lankford argues that while some animals engage in costly and potentially risky behavior to save/benefit their kin, intentional self-sacrifice – where the animal dies as a direct result of the altruistic behavior – does not appear to be common in the animal kingdom (see Lankford 2015).

Moreover, the observations that the families of some suicide terrorists often come from middle-class backgrounds, do not appear to be in need of money, and do not always receive benefits or increased social status have been interpreted as anecdotal evidence refuting the kin selection explanations (Lankford 2015). Lankford (2015) also argues that the fictive kin interpretation of suicide terrorism is problematic since some individuals decide to become a suicide terrorist before joining a terrorist organization. In an attempt to consolidate the fictive kin interpretation with Lankford’s observation, it is possible that for some individuals, the global Muslim community

(referred to as the *Ummah* among Muslims) – not just members of one’s terrorist organization – are perceived as fictive kin. This explanation could shed light on why some individuals decide to become a suicide terrorist before joining a terrorist organization (i.e., the perpetrators of the London 2005 suicide bombings). Moreover, the notion of the global Muslim community as fictive kin could also explain why perceived injustice against Muslims around the world appears to have been a central motivating factor underlying the September 11 attacks and the London bombings.

Multiple Causes of Suicide Terrorism and the Need for Empirical Psychological Research

This review of current psychological and evolutionary psychological perspectives on terrorism and suicide terrorism suggests that there are multiple explanations for these phenomena. The aforementioned explanations represent some of the most dominant accounts and are by no means exhaustive. Despite a preoccupation with identifying the causes of terrorism in an effort to inform counterterrorism strategies, there is currently no consensus among academics about which explanation is best or most “true.” Psychological factors, which are partly rooted in our evolutionary psychology, provide plausible explanations for why some individuals engage in acts of terrorism and suicide terrorism, but there are likely multiple causes or risk factors which might trigger specific evolved psychological mechanisms in different contexts. For example, if an individual has close family members or friends who have been killed by their “enemy,” negative emotions and a desire for revenge, which appear to be evolutionary adaptive, might be a sufficient motivation to engage in terrorism or suicide terrorism.

In other instances, individuals might be motivated by the prospects of personal rewards in the afterlife, personal significance gain, or benefits for their family. Other individuals might have undergone long periods of indoctrination, thus being exposed to manipulation of kinship cues, thereby strengthening a sense of commitment to the terrorist organization and its goals. The observation that many individuals involved in terrorism have

not personally experienced state oppression or military intervention by the West, but claim to be avenging the atrocities perpetrated against Muslims elsewhere, suggests that group identification processes might also play a key role. The diversity of explanations regarding the psychological underpinnings of suicide terrorism and terrorism more generally suggests that there are different types or subgroups of terrorists and suicide terrorist and hence different pathways to involvement in terrorism. Although there might be certain evolved (universal) psychological mechanisms which can shed light on many aspects of engagement in suicide terrorism, a combination of individual, social, and structural factors is likely to interact with these evolved psychological mechanisms to pave the way towards involvement in terrorist organizations and engagement in suicide terrorism.

It is important to remember that much of the early research on terrorism and suicide terrorism has been largely based on theorizing and anecdotal evidence. This means that psychological research has yet to meet the increasing and current demands for terrorism research. However, the logistical and ethical problems in gaining access to terrorist organizations or former terrorists need not preclude future investigation of the psychological underpinnings of suicide terrorism. In recent years, there has been a growing recognition among researchers within the fields of social and cognitive psychology that theory-driven research examining the propensity for intergroup violence and self-sacrificial altruistic behavior can be examined in large, population-based studies (i.e., Obaidi et al. 2019; Zmigrod et al. 2019). One advantage of examining such propensities for intergroup violence and self-sacrificial behavior, among large population samples, is that this approach enables researchers to control for key confounding variables and enables them to use a range of validated scales or tests. Obviously, findings from such population-based studies must be interpreted in light of the existing research on suicide terrorists and terrorist organizations, and the converging validity of the findings would need to be assessed.

Conclusion

Scholars have examined whether suicide terrorism and terrorism more generally might be partly attributable to evolved psychological mechanisms. These scholars have considered how violent group behavior and intentional self-sacrificial behavior could be conceived of as adaptive. Terrorism and suicide terrorism in particular are often connected to non-state organizations with specific political goals, often in response to perceived oppression or existing ethnic or religious conflicts. As such, from a psychological perspective, terrorism can be considered a manifestation of revenge triggered by negative emotions (i.e., humiliation, anger), often tied not only to personal experiences but to the experiences of one's social group. From this perspective, terrorism can therefore be understood as a form of violent collective action to defend one's social group/organization. While revenge and violent collective action might initially be perceived as evolutionarily maladaptive, some scholars have considered whether suicide terrorism could be a form of altruism, thus, drawing on existing models of altruism from the field of evolutionary psychology. Specifically, suicide terrorism has been interpreted as a form of indirect reciprocal altruism, contingent on an illusory contract between the potential agent of suicide terrorism and the organization. An alternative explanation draws from kin selection theory and assumes that individuals engage in suicide terrorism in order to gain benefits for their (genetic) relatives, hence increasing the likelihood that their genes will be passed onto future generations. Others have suggested that suicide terrorism might have evolved as a by-product of kin selection, such that the presence of kin recognition cues might trigger individuals to perceive members of their terrorist organization as "fictive kin."

Evolutionary psychological explanations of suicide terrorism have been criticized on the grounds that intentional self-sacrifice is not common among animals and that this behavior would not have been selected for. Furthermore, some anecdotal evidence suggests that for some individuals who have engaged in suicide attacks, potential benefits for kin do not appear to be a motivating factor. The aforementioned frameworks provide some

plausible explanations regarding the psychological mechanisms underlying involvement in terrorist organizations and engagement in suicide terrorism. However, much of the research on suicide terrorism – and terrorism in general – is based purely on theorizing and observations of individuals who have been involved in terrorist organizations. It is likely that there are multiple causes or risk factors for engagement in suicide terrorism and involvement in terrorist organizations, which influence certain individuals under certain conditions. However, a proper understanding of the complex interplay between different psychological mechanisms behind suicide terrorism and terrorism more generally will require more rigorous empirical research examining the personality, social, and evolutionary psychological underpinnings of intergroup violence and self-sacrifice. One approach to reach a more nuanced and systematic understanding of the role of these diverse psychological underpinnings is to examine the key psychological factors – and how they may interact – in large population-based samples, which should in turn be interpreted in light of existing evidence on terrorists. Only when the results of many empirical, population-based studies converge with existing evidence on actual terrorists can more definitive conclusions be made regarding the role of specific psychological mechanisms underlying involvement in terrorist organizations and engagement in suicide terrorism.

Ensemble representation; Incidental encoding; Statistical summary; Visual awareness; Visual statistical representation

Definition

The phenomenon of readily deriving information from the natural world through the visual system that often lies outside consciousness.

Introduction

Humans are sensitive to the summary statistics of the visual world. They derive this information

from complex scenes, often without explicit awareness. The visual system is susceptible to summary statistical stimuli about group or ensemble characteristics in the natural world. The summary statistics are derived across a host of visual domains, ranging from average orientation to the average expression from crowds of faces. The ease with which people can detect an outlier suggests their representations of categories of objects incorporate some notion of what is average and of the upper and lower limits in the normal variability within the dimension in question. When viewing a set of objects, a particularly large or small member of the set will stand out and will be readily detected (Hodsoll and Humphreys 2001).

Memory and Personality Traits

Not only can one have knowledge about the circumstances of one's life, but one can also have semantic knowledge about one's own personality traits. Klein and Loftus and their colleagues (Klein et al. 2001) proposed and tested a model of the relation between memories of personal experiences and trait conceptions of self. Their model incorporated the following three features. First, long-term knowledge of one's traits is abstracted from multiple experiences with trait-relevant behaviors and represented in semantic memory in summary form. Second, trait judgments about the self are made by accessing these summary representations without reference to the behavioral episodes from which they were derived. And third, summary trait representations are functionally independent of memories of trait-relevant behavioral episodes. There now is ample evidence that people form summary representations of their own personality traits and retrieve these when asked to decide whether a particular trait describes them. Equally important, a large body of evidence shows that people maintain detailed stores of behavioral episodes they have experienced.

Scope Hypothesis

According to the scope hypothesis, deciding whether a trait is self-descriptive activates a

summary representation and episodes inconsistent with the trait being asked about. The decision context should determine when boundary conditions are needed, and which kinds of episodes would be relevant. Because decisions regarding personality traits are not amenable to all-or-none answers, it would be reasonable to assume that the trait summary takes a quasi-quantitative form.

Thus, when the individual is asked if a certain trait describes them, possible answers might be "usually," "sometimes," or "rarely." Boundary conditions would be episodes in which the behavior did not meet the criteria for that trait. This should be true for any level the trait summary specifies, even "rarely." This is because the decision context calls for a generalization about it; the function of activating episodes is to place boundary conditions on that generalization. The issue is, "How often is Person Y friendly, and under what conditions is she or he not?" The decision rule activated is designed to make a judgment about the trait being asked about, whether the question originates with another person or with the individual making the judgment.

Different decision rules are designed to retrieve different kinds of information from memory. The type of decision being made matters, because that determines which search engine gets activated, which will determine which array of memory systems gets searched. When asked to trait-categorize their own behavior, subjects should retrieve a trait summary and episodes inconsistent with the trait they are being asked about.

The Statistical Nature of Summary Representation

Research suggests that when subjects attend to a particular dimension of a set of items presented over an extended duration, they quickly learn about the central tendency of the set. However, it is unclear whether such learning can occur incidentally, when subjects are not attending to the relevant dimension of the set. Chris Oriet and Kadie Hozempa (2016) studied incidental summary representation over time exploring whether subjects could reproduce global statistical properties of a set presented over an extended duration

when oriented to task-irrelevant properties of the set. Subjects were tested for their memory of its mean, its smallest and largest exemplars, the direction of its skew, and the relative distribution of the items. Subjects were able to accurately recall the average size circle, as well as the upper and lower boundaries of a set of 4200 circles displayed over an extended period. This suggests that even without intending to do so, they were encoding and updating a statistical summary representation of a task-irrelevant attribute of the circles over time. Such incidental encoding of statistical properties of sets is thus a plausible mechanism for establishing a representation of typically in category membership.

Change Blindness

The failure to notice differences in sequential scenes or images is a well-established phenomenon, suggesting that humans have a limited visual awareness from one moment to the next (Mitroff et al. 2002; Rensink et al. 1997). Although, on the surface, change blindness seems to suggest a sparse visual representation, an abundance of recent research has supported the notion that a failure to represent visual information is unlikely to drive this phenomenon. Much of the incoming visual input is preserved in spite of change detection failures (Beck and Levin 2003; Hollingworth 2003). For instance, Beck and Levin (2003) showed that observers could identify an object change in the absence of a durable representation of that object. Mitroff et al. (2004) demonstrated that this durable representation could potentially be used to aid in object identification. Hollingworth and Henderson (2004) found that visual scene information was preserved even when observers failed to detect a rotation in the scene. Research suggests that despite the limited conscious access revealed by change detection experiments, the “gist” of a scene remains accessible (Oliva and Torralba 2001; Potter 1976; Thorpe et al. 1996).

Given the fundamental and ubiquitous nature of summary statistical representation, Jason Haberman and David Whitney (2011) tested whether this kind of information is subject to the

attentional constraints imposed by change blindness. They showed that information regarding the summary statistics of a scene is available despite limited conscious access. In a novel experiment, they found that while observers can suffer from change blindness (i.e., not localize where change occurred between two views of the same scene), observers could nevertheless accurately report changes in the summary statistics about the very same scene. In the experiment, observers saw two successively presented sets of 16 faces that varied in expression. Four of the faces in the first set changed from one emotional extreme to another in the second set. Observers performed poorly when asked to locate any of the faces that changed (changed blindness). However, when asked about the ensemble (which set was happier, on average), observer performance remained high. Observers were sensitive to the average expression even when they failed to localize any specific object change. That is, even when observers could not locate the very faces driving the change in average expression between the two sets, they nonetheless derived a precise ensemble representation. Thus, the visual system may be optimized to process summary statistics in an efficient manner, allowing it to operate despite minimal conscious access to the information presented.

The Role of Attention

As the perceptual phenomenon occurs when a change in a visual stimulus is introduced, the observer does not notice it. Observers often fail to notice major differences introduced into an image while it flickers off and on repeatedly. Researchers have found that shifting a person's attention, such as causing distraction, leads to increased change blindness. There is already evidence that summary statistical information operates beyond the focus of attention (Alvarez and Oliva 2008). Nonetheless, this has only been demonstrated with low-level features, such as features thought to be analyzed at the earliest stages of cortical visual processing, including orientation, contrast, and motion direction, which are expected to be processed in parallel (Watamaniuk and McKee 1998).

Conclusion

Information taken in by the human visual system allows individuals to form statistical representations of sets of items. One's knowledge of natural categories includes statistical information, such as average size of category members and the upper and lower boundaries of the set. An abundance of research suggests that subjects can represent statistical properties of small sets of items presented simultaneously or over a period of a few seconds. It is also argued that statistical properties can be extracted for sets of items encountered over time, when subjects attend to the measured attribute. This type of statistical summary learning appears to occur without conscious intent.

Supernormal Stimuli

Deidre Barrett

Harvard University, Cambridge, MA, USA

Definition

Supernormal stimuli are any stimuli that elicit an instinctual reaction more strongly than does the stimulus for which the instinct evolved.

Introduction

Ethologist Niko Tinbergen won the 1973 Nobel Prize in Biology for his research on instinctive behavior in animals. Tinbergen used various dummies to elicit nurturing, mating, and fighting behaviors. He and his students constructed fake eggs which birds would sit on, artificial female butterflies which male butterflies courted, and models of male fish which other males attacked. Some of the dummies were ingeniously *unrealistic* to elucidate exactly what characteristics triggered the behaviors. Territorial male stickleback fish will not attack a fish-shaped model if its belly isn't red, but they violently pursue some very unfish-like models when the underside is red.

Perhaps the most interesting of Tinbergen's discoveries is that dummies can be devised which surpass the power of any natural stimuli. Tinbergen coined the phrase *supernormal stimuli* for these dummies that elicit stronger responses than occur naturally.

Animal Research

The supernormal stimuli which eventually received the most study were decorated plaster eggs. Tinbergen found that most bird species preferred eggs that were larger than their own and ones which had exaggerated colors or markings. The oystercatcher, which lays small brown-specked eggs, will ignore them in favor of a giant brown plaster egg the size of the bird itself.

Song birds abandon their pale blue eggs dappled with gray to hop on a black polka-dotted Day-Glo blue dummy so large that they continuously slide off and have to climb back on. Ground-nesting birds will retrieve eggs dislodged from the nest, rolling them back into place. When given a choice between its own egg and a *volleyball*, the greylag goose ignores the egg and tries valiantly to roll the volleyball into the nest.

Tinbergen noted that there's at least one bird which has evolved to be essentially a supernormal stimuli to other species. The cuckoo lays its egg in another bird's nest, where the unsuspecting foster parents incubate and feed it, leaving the mother cuckoo free to fly off to lay more eggs. The baby cuckoo is actually given preferential treatment over the host's offspring. The cuckoo egg is usually larger than the host's so it is sat on more consistently than the other eggs in the nest. When hatched, the young cuckoo's wider throat acts as stronger stimuli to the feeding mother than her own chicks.

He studied butterflies and found that marks on the torso of the female and its vibratory movements were the sole mating releasers – he could construct dummy butterfly torsos with brighter stripes and more regular movements. Males would ignore a live, receptive female to mount cardboard cylinders that didn't even need wings!

Tinbergen also studied the stickleback fish whose males are highly territorial. He and students spent hours leaning over the tanks, “swimming” the dummies around. At first these were just dead fish on wires, later they carved and painted wooden ones. Systematically varying the wooden models, they established that it was redness of the underbelly that signaled “male-to-attack.” Sticklebacks didn't attack a realistically shaped model if its belly wasn't red, but violently pursued *very* unfish-like shapes with red undersides. Males in aquariums by the window went into attack mode when a red *postal van* drove by.

Color wasn't the determinant for detecting females; males escorted carved wooden models to the nest if they had the curved belly of an egg-bearing female. They preferred the model with the roundest stomach.

The stickleback models could easily be made to be supernormal. Male sticklebacks ignored a real male to fight a dummy brighter red than any natural fish. They'd choose to escort an exaggeratedly round-bellied model over a real egg-bearing female. For every species and instinct Tinbergen studied, he could successfully produce supernormal stimuli once the eliciting releasers such as shapes, colors, and scale were discovered.

Human Implications

Tinbergen made clear in brief comments that he thought supernormal stimuli applied as much to humans as to other species, but he did not develop this as he was usually writing about fish, birds, and insects. More recently, evolutionary psychologists have begun using the term in describing human behavior. Deirdre Barrett points out that while animals encounter supernormal stimuli mostly when experimenters build them, humans produce their own, and in the technological age, they're becoming ubiquitous: candy, pornography, huge-eyed stuffed animals, and diatribes about menacing enemies.

She argues that supernormal stimuli are a driving force in many of today's most pressing problems, including obesity, our addiction to television and video games, and the past century's extraordinarily violent wars. Man-made imitations radically alter what food humans put into their bodies, how sexuality is expressed, and if and how wars are fought. A unique implication for humans when they become aware of supernormal stimuli is to apply logic and willpower to override instincts in a manner a bird on a bright blue egg cannot.

Conclusion

The key point is that *supernormal stimuli reverse the natural relationship between instinct and object*. This makes for an interesting technique in illuminating animal instincts but creates problems for humans who create them prolifically.

[Artificially exaggerated stimulus](#); [Optimally primed stimulus](#); [Super-stimulus](#); [Supernormal sign stimulus](#).

Definition

Supernormal sign stimuli – a term invented by Niko Tinbergen and now usually abbreviated simply as supernormal stimuli (1951, 44) – are exaggerated/heightened imitations of naturally evolved phenomena/objects that exert a stronger attraction/desire on their target audience than the natural phenomena/objects themselves (Barrett 2010, 3). According to Tinbergen, the phenomenon was first reported by O. Koehler and A. Zagarus (1937), but it was then further developed by Tinbergen together with his colleague Konrad Lorenz. An example of a supernormal stimulus from the natural world is the cuckoo egg. Cuckoo eggs appear very similar to those of their host but are usually somewhat larger and/or brighter.

It has been suggested in evolutionary terms that “instances of supernormality may reflect the action of two factors during phylogeny:

(a) asymmetrical selection pressure with respect to responsiveness to the relevant stimulus continuum (e.g., size, speckledness), and (b) independent selection pressures limiting the corresponding properties of the natural stimulus” (Staddon 1975, 541). As explained by Tinbergen, this means that a naturally evolved situation/item is not always stimulus-optimal (1951, 44).

Konrad Lorenz and Niko Tinbergen

Together with Niko Tinbergen (1907–1968), Konrad Lorenz (1903–1989) was one of the two most important founders of the modern ethology movement. Lorenz’s key significance for ethology has been outlined as follows:

The target of [Lorenz’s] investigations was at first the innate motor pattern . . . He investigated the key stimuli that release a specific behavior prior to all experience and studied the phylogenesis and ontogenesis of innate behavior patterns. In the “instinct-learning intercalation” he found a new mode of integration of innate and acquired components of behavior, and in the phenomena of imprinting he discovered an inborn disposition to learn (Eibl-Eibesfeldt 1975, 7).

Lorenz’s use of the instinct concept in ethology was taken up directly and developed by Niko Tinbergen, most significantly in an important book presenting his work on the investigation of innate behavior, *The Study of Instinct* (1951).

In the 1940s/early 1950s, Tinbergen was also studying the behavior of the three-spined stickleback, the most common freshwater fish in Holland. As has been explained about the results of this stickleback behavioral study:

The most interesting of Tinbergen’s discoveries was that dummies could surpass the power of any natural stimuli. Male sticklebacks ignored a real mate to fight a dummy brighter red than any natural fish . . . Tinbergen named the phenomenon of his exaggerated dummies “supernormal [sign] stimuli”. He published papers outlining the concept that instincts were coded for a few traits and amplification of these traits could easily fool animals (Barrett 2010, 12–13)

In fact as Tinbergen readily acknowledged, he did not discover the concept of supernormal stimuli but he did investigate it in more depth than had

previously been undertaken, and he did more explicitly recognize its wider significance for understanding animal behavior.

Examples of Supernormal Stimuli

Some of the specific animal-related examples of supernormal stimuli that have been presented in the literature are: dummy eggs with exaggerated size, color, and markings, e.g., geese eggs and song-bird eggs, that induce preferred brooding behaviors; dummy females with exaggerated sexually selected features that induce preferred mating behaviors; artificial herring gull food-begging stimuli with heightened colors that induce preferred feeding behaviors (Tinbergen and Perdeck 1950); beer-bottles studded with glass beads that induce preferred mating behavior in some beetles; and exaggerated signal behaviors induced by parasites in order to manipulate their baby bird hosts.

Supernormal stimuli are not only relevant to studying animal behavior but are also relevant to understanding the behavior of human beings. For example, it has been hypothesized that one instance of a supernormal stimulus is the waist-to-hip ratios of human females that are most preferred by males:

A possible human analog [of a supernormal stimulus] is men’s sexual preference for very low WHRs [Waist-to-Hip Ratios]. A female WHR of 0.6 – which is within the human female range, but extremely rare – is perceived as more attractive than a WHR of 0.7 (Singh 1994) . . . Perhaps in the human EEA there was no such thing as a woman with too low a WHR . . . [and] selection favored a simple psychological mechanism instantiating the rule “lower is better”, and the maximally attractive WHR thus is supernormally low (Symons 1995, 111).

In fact a large range of sex-related behaviors and associated sexual enhancement products can be interpreted within the framework of the supernormal stimuli concept, including pornography for men and romance novels for women.

Other specific human-related examples of supernormal stimuli that have been discussed in the literature are: women’s high-heeled shoes (Morris et al. 2013); various fast-food items such

as hamburgers and pizzas (Saad 2011); narcotic drugs such as cocaine and heroin (Barrett 2010, 78); and contemporary Islamic terrorist attacks (Geher 2015). All of these examples of supernormal stimuli aim to employ evolved psychological mechanisms and to manipulate them for specific ends by presenting heightened or extreme forms of a preexisting natural phenomenon or behaviors.

For example, high heels work by exaggerating the natural movement of female hips as women walk; fast food works by presenting more concentrated examples of what human beings naturally desire to consume: meat, sugar, and fat; narcotic drugs work by the heightened activation of pre-existing neural pleasure-circuitry in the brain; and contemporary terrorism works by playing on/exaggerating preexisting fears of sudden and uncontrollable predator attacks that produce death or very serious injury.

Pornography and Mirror Neurons

One example of a supernormal stimulus that is viewed by some as having negative effects is pornography. As has been explained:

Sex is an obvious target for supernormal stimuli . . . everything from pornography to advertising models, from plastic surgery to old-fashioned cosmetics, cinched waists, and padded bras can be seen as people amplifying nature's signalling (Barrett 2010, 30).

Pornography acts as a supernormal stimulus (for men) by portraying female sexuality in a heightened or "amplified" form. Contemporary pornography actresses are usually more beautiful than the average woman, they are (in their porn performances at least) more sexually compliant than them, and they are shown as being more frequently available for sex. It can be hypothesized from the "immersive" nature of pornography consumption that it functions in part through the activation of mirror neuron circuits that have evolved in various primates (including Hominids) over evolutionary "deep time."

As has been explained, the term mirror neurons designate "a group of interconnected neurons that fire (differentially) for the observation, execution,

and . . . imitation of goal-directed motor behaviors involving objects" (Wallis and Wright 2009, 283). Mirror neurons, a variety of visuospacial neuron, fire both when an action is being performed by an individual and when the same action is observed being performed by someone else. They can also be activated when one individual observes another individual performing a specific action, and the first individual is also simultaneously performing the same action as the second (Rizzolatti and Fogassi 2007, 179). By this means, these mirror neurons "give the observer access to the goal of the action and thus put [them] in the place of the performer of the action" (Gold and Roskies 2008, 364).

Evidence that mirror neurons are involved in pornography consumption can be deduced from the fact that when some types of male monkey are shown pornographic imagery of other monkeys having sex, their testosterone level can rise by as much as 400%, testosterone levels being directly linked to sex-drive (Winston 2002, 154). The fact that mirror neurons exist in primates and human beings can be taken as evidence that natural selection has, over a significant period of time, favored some types of behaviors that are performed by individuals in imitation of other animals, and that this imitation process sometimes serves the function of a stimulus enhancement (Visalberghi and Frigaszy 1990, 249).

Can Supernormal Stimuli Be Adaptive?

The subtitle of Deidre Barrett's book on *Supernormal Stimuli: How Primal Urges Overran Their Evolutionary Purpose* (2010) could be taken to imply that supernormal stimuli are an inherently negative development. As Barrett explained, "Animals and man are indeed often harmed by what they desire . . . the supernormal stimulus" (Barrett 2010, 136), but they are not inevitably/always so. It is true that supernormal stimuli *can* have negative consequences in some instances but in other instances they might have positive consequences. It is also possible that they can produce both negative and positive consequences simultaneously.

It might also be asked: Can particular supernormal stimuli ever serve an adaptive function in the Darwinian sense? What might an adaptive function of pornography look like? One plausible candidate for an adaptive function of porn is: to facilitate greater understanding of sexual behavior/interaction so as to improve reproductive fitness by means of improved sexual performance. Or, as has been outlined elsewhere, an adaptive function of pornography could be to make its viewers “sexually aroused in a way that they gain new insight into their own sexuality and desires,” other people’s sexuality and desires, and in consequence the full range of human sexuality in all its varied forms (Maes 2012, 17). Mirror neurons may also assist in this process by enabling better understanding of other people’s sexuality and desires.

This hypothesis assumes that sexual satisfaction, in addition to just reproductive success, is something that all human beings value and is therefore a central part of universal human nature. Behaviorally successful sex can be seen to assist in strengthening the relationship bond between couples, this bond being part of a wider need for the development and maintenance of compatibility between sexual partners.

Within the Darwinian framework, achieving sexual pleasure for both sexes is what evolution would select for (Wells 1989), as it leads to greater reproduction rates. As Charles Darwin explained in his autobiography on the link between pleasure and function:

Pleasurable sensations . . . stimulate the whole system to increased action. Hence it has come to pass that most or all sentient beings have been developed in such a manner through natural selection, that pleasurable sensations serve as habitual guides. We see this in the pleasure from exertion . . . of the body or mind, – in the pleasure of our daily meals, and especially in the pleasure derived from sociability and from loving our families (Barlow 2005 [1887], 74–75).

Better promoting the sexual satisfaction/pleasure of a partner can be seen potentially to serve a Darwinian function, as greater happiness promotes better mental health and thereby greater reproductive success. Supernormal stimuli may, therefore, in certain instances serve a positive function.

Conclusion

The concept of supernormal sign stimuli was initially developed by Niki Tinbergen and Konrad Lorenz as part of the mid-twentieth century ethology program, but more recently it has been usefully employed by contemporary evolutionary psychologists such as Donald Symons (1995), Diedre Barrett (2010), and Gad Saad (2011).

Many different contemporary phenomena have been characterized as supernormal stimuli, and it would be possible to suggest that applying the term to one or two of them – contemporary Islamic terrorism, for example – might be stretching the reasoned applicability of the concept beyond its useful limit. However, it is beyond any doubt that most of the other contemporary applications in the literature – high-heeled shoes, fast food, and pornography, for example – are appropriate uses and therefore the supernormal stimuli concept has proved itself to be a very useful and a scientifically valid one.

Even so, despite the sex-positive case outlined in this entry, it will remain controversial to characterize pornography as an adaptation in the Darwinian sense, as even the existence of this supernormal stimulus is controversial for some, as is the hypothesis that pornography functions through the activation of mirror neurons. But, as has been explained: “Control over . . . erotic imagery for social ends is nothing new. It began more than 30,000 years ago, during the last ice age” (Taylor 1996, 96), so critics of pornography might find themselves disappointed if they expect this particular supernormal stimulus to disappear from the transmitted cultural horizon anytime soon.

Synonyms

Artificial stimulus; Supernormality

Definition

An artificial stimulus capable of eliciting an innate, instinctual stimulus-response more powerfully than the original natural stimulus for which the response is adaptively intended.

Introduction

Our minds evolved as a set of psychological mechanisms, each designed by natural selection to solve a particular adaptive problem. Different stimuli activate different mechanisms, thus eliciting different responses. Unfortunately, this also means that our information-processing machinery is prone to certain kinds of errors because natural selection shaped our brains to interpret the world in an adaptive fashion and not necessarily in a truthful manner. As a result, and particularly with the rapid change between our environment of evolutionary adaptedness and today's artificially made environment, some unnatural stimuli can activate the same mechanisms that naturally evolved stimuli do. These unnatural stimuli are referred to as supernormal stimuli, a term coined by early ethologist Nikolaas Tinbergen.

From Early Ethology to Today's Consumerism

Supernormal stimuli mimic and exaggerate response-producing qualities of natural stimuli

beyond the proportions of what was ancestrally possible. They are usually associated with the ability to sway behavioral preferences away from natural stimuli and in favor of artificial constructions. In this way, preferences that would have been beneficial during ancestral conditions may be manipulated to the detriment of an acting organism.

Tinbergen and Perdeck (1951) observed the effects of supernormal stimuli on sea gull behavior when he successfully elicited a behavioral preference toward exaggeratedly bright-red models of an adult gull's beak. Typically, newly hatched chicks are stimulated by a red spot on the mother's beak, as pecking this spot induces regurgitation. Tinbergen then constructed different beaks, each model exhibiting an even bigger spot to the point that some models barely even resembled a beak at all. Chicks recurrently preferred the exaggerated, unrealistic beaks over the models accurate to an adult gull's morphology. Additionally, other animal species showed similar responses. Small songbirds that lay light blue grey-dappled eggs preferred to sit on bright blue black polka-dotted dummies, even when these were so large that their bodies slid off them repeatedly. Similarly, territorial male stickleback fish would attack wooden floats with red undersides, attacking extremely red floats more vigorously than they attacked actual invading males.

Barrett (2010) suggested that supernormal stimuli offer an explanation for several potentially detrimental human behaviors, including the preference for highly concentrated sugars and fats, pornography and breast augmentation, aggressive property defense, and television. These are all examples of stimuli that are naturally sought after and wanted by humans, but are exaggerated from their original forms to be superficially appealing. This is also an example of the *evolutionary mismatch* effect in things such as sugars and fats. In ancestral times, early hominins needed to survive on a very short food supply. Therefore, sugars and fats were extremely valuable given their ability to be stored and thus represent a better chance at survival by being satiated for longer. In addition, they were rare enough that it was

practically impossible to be consumed to excess. Now, we have the ability to simply walk to our local grocery and pick up sugars and fats in exchange for money. Given this ease and simplicity, it is extremely easy to overconsume sugars and fats, whereas it would have been impossible to in ancestral times. The sugar content is also so high compared to what would have been available to our ancestors that it becomes very easy to overindulge, a classic example of supernormal stimuli. The overconsumption then leads to negative impact on our health and to detriments such as heart disease, diabetes, cancer, and so forth. While not all supernormal stimuli are necessarily harmful for our health, sugars and fats are a clear example of how supernormal stimuli can take advantage of consumers and is the basis for much of how products are sold.

Conclusion

Supernormal stimuli are artificial stimuli that elicit an instinctual response more powerfully than a natural stimuli would. This is apparent in birds such as gulls, with their response to a red dot stimuli of any kind being the same as if they actually saw the red dot on their mother's beak. The same effect is apparent in humans and is a basis for consumerism, as much of what sells is a result of our adaptive responses to stimuli being superficially exaggerated to elicit a want to engage with the said product. Things such as sugars and fats, pornography, and television are all examples of things that utilize supernormal stimuli to sell their product and take advantage of humans' natural propensity toward certain stimuli.

Definition

Research tools that systematically collect information using a variety of methods.

Introduction

Surveys are a systematic way to collect information and data about the same variables for multiple individuals, which can then be compared. While methods of data collection within surveys can vary, questionnaires are commonly used. Questionnaires are a series of questions which are used to collect responses regarding demographics, emotions, behaviors, and/or thoughts. Researchers can choose if they want responses to be made from a set of options, such as in Likert-type scales, or if they want the questions to be open ended, such that the participant formulates their own answer which is often coded to a scale afterward. Surveys and questionnaires can be administered either in person or remotely, using a variety of methods, such as paper and pencil, telephone, electronically through the Internet, or a combination thereof.

There are several benefits to utilizing surveys. One of the most well-known advantages of

surveys is their efficiency in collecting data. Although some methodologies, such as interviews, may have more difficulty in collecting a broader sample, surveys allow for random sampling within particular populations which gives researchers better opportunities to generalize their findings. When considering the costs of distribution and participant compensation, surveys help keep these costs low. Surveys also provide ethical benefits in regards to anonymity. In particular, self-administered questionnaires can give participants an opportunity to feel more comfortable giving information on sensitive topics. Lastly, surveys have the ability to be flexible in regards to the goals of the researcher.

Although surveys are widely used and provide many benefits to both the researcher and participants, there are issues that should be noted. First, participants may not respond to every question that is given to them, leading to the possibility of missing data. The probability of this occurring depends on the methodology used and what information the surveys are asking for. For example, when seeking sensitive information, participants will be more likely to withhold their responses. Secondly, there are various responses that participants can provide that may not accurately reflect the researcher's intentions. This is known as response bias and is described further in the entry Response Bias within this book.

The means by which a survey or questionnaire is initially constructed is paramount to any research using these methods. As mentioned above, surveys and questionnaires, while having many advantages, also have numerous potential weaknesses. Many of these weaknesses can be avoided or at least mitigated if the research tool is constructed carefully and thoughtfully. Before a measure's construction begins, it is extremely important to carefully specify the research question of interest and the hypotheses to be tested, the analyses that will be performed to test these hypotheses, and the construct that is to be measured. Doing so will allow the measure to perform as accurately and efficiently as possible. Other, more specific suggestions are mentioned below.

Keep Your Target Population in Mind

Make sure to consider both the expected abilities and values of your target population when constructing your measure. Doing so includes considering the language proficiency of your target population. The complexity of the language used in your measure must match the abilities of those with whom you are communicating. For research involving undergraduate students, it is likely safe to assume that the participants are fairly advanced in their language skills. For research with younger children or less educated adults, simpler, more straightforward should be employed. Similarly, avoid using jargon whenever possible; you should only use language that you can reasonably expect your target population to be familiar with. Additionally, take care to avoid phrasing your questions in such a way that it could offend your target population. Make sure to use the currently accepted neutral vernacular when referring to any subgroups as well as neutral language when writing about any personal topics (e.g., a participant's religious orientation).

Construct Your Questions Purposefully

Only ask questions that are of theoretical interest to your research. Unimportant questions are taxing for the participants and the researchers alike. Only include "filler" questions if there is good reason to think that the data may be biased without them. Make certain that your questions are unambiguous in their meaning. If different participants interpret the same question in different ways, the validity of your measure can suffer drastically. Avoid "double-barreled" questions that ask more than one thing at a time (e.g., "how likely are you to lease a new car and a new home in the next 12 months?"). Include enough response options to fully cover the potential range of responses. It is possible that this may require you to have one option that reads "other" with a blank space to allow the participants to fill in their own responses. Similarly, the response options should be mutually exclusive; allowing the responses to overlap can confuse participants and reduce the

precision of your data. When possible, measure responses on a continuous scale rather than an ordinal or categorical scale (e.g., do not ask participants to select an age bracket when it is just as simple to ask for a date of birth). This will only serve to increase the quality of the data that is collected and will allow for more sophisticated analyses to be conducted. Present all questions in a neutral way that does not lead the participant to choose any option over another. Lastly, be cognizant of response biases and either construct your questions in such a way to avoid them or employ additional means (e.g., detailed instructions asking your participants to be mindful of how they are responding) to help avoid these potential issues.

Verify That Your Efforts to Avoid Bias Have Been Adequate

While the non-exhaustive set of advice above will help to avoid or mitigate some issues in using surveys and questionnaires, it can be difficult to know if these preventative measures have been enough to ensure your data will be of acceptable quality. Fortunately, there are a variety of ways to assess the reliability and validity of your measure and whether additional refinement is needed. A few of the most widely used techniques will be listed here to guide future research, but a detailed explanation of these methods is beyond the scope of this entry.

Consult experts and previous research. When possible, it can be fruitful to consult experts in the field to request both suggestions and critiques for your instrument at any stage of development. Additionally, it is not always necessary to build a measure completely from the ground up. Consult previously constructed measures, should they exist, and build upon them rather than seeking to completely replace them.

Pilot test your measure. It is valuable in any study, whether surveys and questionnaires are employed or not, to pilot your measure(s) on a small sample of your target population. This can help to identify many of the problems described above, as well as potential errors in measure

implementation (e.g., an online survey unexpectedly skipping a large portion of the questions).

Utilize test-retest techniques. This can easily be done in conjunction with piloting your measure. If responses that are expected to be reliable are shown to not be, then your measure is not ready for implementation in a study.

Employ multitrait-multimethod techniques. Multitrait-multimethod (MTMM) matrices can be used to examine both the convergent and discriminant validity of a measure when compared to other existing measures. Should other measures exist that examine the same construct as your survey or questionnaire as well as ones that measure other distinct constructs, you can use MTMM techniques to assess the content validity of your newly created measure. For an explanation of MTMM matrices and how to implement them, see Campbell and Fiske (1959). For an additional adaptation of these approaches, see Centra (1970).

Conclusion

Surveys and questionnaires are valuable and popular research tools that capitalize on speed and efficiency of data collection across a wide array of participants. These tools also have a number of potential limitations that may not be issues for other measures. As such, researchers must be cognizant of the measures they use and especially those that they create. Mindful construction of the items used can greatly mitigate many of the potential limitations of surveys and questionnaires.

Survival Advantages of ADHD Symptoms Based on Evolutionary Mismatch Approaches

Benefits of distractibility; Characteristics that help one stays alive; Traits that facilitate continued existence; Usefulness of hyperactivity

Definition

Symptoms of attention deficit hyperactivity disorder (ADHD) are regarded by evolutionary mismatch theorists as prehistorically useful traits that have become broadly nonadaptive in the present world as a result of evolutionary time lags.

Introduction

ADHD is a condition which is generally typified by an enduring tendency for the sufferer to be extremely active, distractible, and impetuous, and that he/she is also prone to be neglectful of his/her tasks at hand (American Psychiatric Association 2013). It is an affliction that has often been associated with a range of adverse consequences (regardless of whether one has received appropriate psychological/psychiatric interventions or not) such as having a greater likelihood of experiencing weight issues, problems with substance abuse, inferior self-respect and psychosocial competence, and

poorer scholastic and career achievements than their healthier counterparts (Shaw et al. 2012). In virtue of these ramifications, many researchers and clinicians have been pulling out all the stops in trying to identify the possible cause (or causes) of ADHD. A variety of mainstream explanations have been advanced, including those that have highlighted the influential impact of distressing experiences in one's early life, the role of genes, and the significance of neurobiological factors (Shelley-Tremblay and Rosen 1996; Swanepoel et al. 2017).

However, because these prevailing hypotheses have mainly focused on clarifying the processes influencing the development of psychological disorders (in this case ADHD) and not why they came about in the first place, there is a real need to take into consideration their evolutionary origins in order to better appreciate the pathogenesis of a disorder such as ADHD (O and Brüne 2019). In this regard, several prominent evolutionary formulations have been proposed with a view to explain the underlying origin of ADHD. These theories are based fundamentally on the premise of evolutionary mismatch, which refers to the phenomenon whereby many modern problems (such as ADHD symptoms) are believed to be a result of genes and cognitive/behavioral mechanisms generally not being capable of evolving expeditiously enough to be acclimatized to a swiftly metamorphosing contemporary world (O 2018).

Leading Evolutionary Mismatch Approaches of ADHD

ADHD Symptoms as Adaptive Hunters' Traits

One such formulation is Hartmann's (1993) notion of ADHD symptoms (e.g., the high amount of energy, impetuousness, and the tendency to quickly shift attention to new stimuli in one's environment) as traits that were helpful for one's survival in a hunting-oriented prehistoric context filled with unpredictability and hazards (as well as opportunities), which are nonetheless regarded as signs of a disorder in the modern world that is more suited for people (or *farmers*) who would prefer greater organization and a more sedentary approach to life. In other words, cognitions and

behaviors typically regarded as ADHD symptoms are posited to be evolved traits useful for prehistoric hunters but are presently mismatched evolutionarily (and hence regarded as problematic) in a farmers-conducive modern world (Hartmann 1993). For instance, the tendency for an individual to shift attention quickly to a new stimulus in one's environment (e.g., a wriggling snake), while doing another task (e.g., preparing a trap) would probably be lifesaving for a prehistoric hunter; however, such a similar distractible tendency might not necessarily be considered beneficial for a child preparing for his/her exams in the much safer present world (especially when the new stimulus is a television program).

Survival Benefits of ADHD Symptoms for Waders

Founded on Morgan's (1972) expanded aquatic ape theory, Shelley-Tremblay and Rosen (1996) put forth a formulation which suggested that individuals with ADHD symptoms were actually more adept at outliving their non-ADHD counterparts during a significant period of prehistory in which *Homo sapiens* were believed to have spent considerable amount of time in water. According to this formulation, children who are more proficient in drawing the attention of their mothers in such conditions (e.g., those with ADHD symptoms who were conceivably very active, especially orally) would be more successful at obtaining food and security from them (as these children could not easily hold on tightly to their caregivers, who have little body hair as an evolved physical reaction to aquatic environments) (Shelley-Tremblay and Rosen 1996). For instance, a mother in that ancestral context might need to pacify the child who is the loudest and is making the most noises first (perhaps by providing some milk or food so that he/she would not attract the unwelcome attention of predators), before feeding her other offspring while in the water (thereby enhancing the survival odds of that child); however, such traits might not be advantageous in the land-based, resource-rich, relatively predator-free present day. In short, ADHD traits might have represented an evolutionarily mismatched set of cognitions and behaviors that is no longer beneficial in the modern, non-aquatic world in which humans generally reside in.

Individuals with ADHD as Better Fighters

Shelley-Tremblay and Rosen (1996) have also suggested that ADHD symptoms might alternatively have evolved as useful traits for physical combats during a period in evolutionary history where humans were believed to have been actively battling with Neanderthals over limited resources, but are predictably much less relevant in the modern, relatively peaceful context. A hyperactive individual would conceivably be a better combatant (and hence more likely to survive a physical fight) than a lethargic one in such conditions; nonetheless, with the advent of laws and law enforcement forces (and therefore a much peaceful environment) in the contemporary world, being a good fighter is generally no longer beneficial nor an essential attribute for one's continued existence.

ADHD Traits Facilitate Swift Reactions

Jensen and colleagues (1997) alternatively contended that ADHD traits were helpful for one's continued existence in certain prehistoric contexts (e.g., especially those that were generally hostile and unpredictable) because those with such traits were more capable of reacting swiftly to (and thus dealing effectively in terms of) surprises and changes in these conditions as opposed to their calmer, more ruminative counterparts. Being capable of noticing and attacking a rabbit rapidly without much forethought for instance (which were more likely among those with ADHD traits than not), might be the difference between survival and death in a hostile prehistoric world where food was infrequently available (Jensen et al. 1997). Such quick reactions might not comparably be as necessary for one's survival in the present context though, especially when most people (at least in industrialized countries) are currently living in largely tranquil conditions with relatively easy access to food (Jensen et al. 1997).

Survival Advantages of ADHD-Associated Capricious Behaviors

In a different vein, Williams and Taylor (2005) propounded that inquisitive behaviors typically exhibited by those with ADHD (especially if they constitute a small proportion of a band) might actually be helpful for the community across prehistory (despite the potential of

incurring some personal harms). Such inquisitiveness was believed to be instrumental in providing conceivably lifesaving knowledge regarding essential tasks (e.g., identifying edible food from those that are inedible or being cognizant of hazards in one's habitat) for one's community in the ancestral period (Williams and Taylor 2005). For instance, other youngsters might have learned to avoid playing with/eating thorny plants (and hence be more likely to avoid injury or even death) after a curious child with ADHD was pricked by one in the prehistoric context. However, given the widespread dissemination of knowledge regarding food (and other survival-related issues) in the present day, coupled with the relative ease of ensuring one's safety on a daily basis (especially for the industrialized part of the modern world), it is logical to assume that (even though the formulation did not explicitly indicate the role of evolutionary mismatch) these inquisitive behaviors are no longer very relevant in enhancing the well-being of a community in the current context.

The Adventurous Nature (and Hence Survivability) of Individuals with ADHD

More recently, Swanepoel et al. (2017) postulated that those who have ADHD traits were better equipped to survive and procreate in the ever-changing prehistoric world because they tended to be more curious, investigative, and enterprising than people without such traits (e.g., eagerly scouting around for alternatives after a natural disaster has rendered one's current residential location uninhabitable). Such traits nevertheless, are believed to run counter to the key philosophy of modern scholastic culture, where students are supposed to be deferential to rules and to pay attention in class while remaining sedentary for long durations (Swanepoel et al. 2017).

Integration of Key Evolutionary Mismatch Approaches

While a number of evolutionary mismatch accounts has been introduced in the literature to explicate ADHD over the years, there are few

research work investigating the veracity of these explanations thus far (Thagaard et al. 2016). However, this does not necessarily suggest that these formulations are misguided or wrong (the few existing investigations have appeared to provide preliminary support for an evolutionary perspective); it merely indicates that additional scientific work are needed to reliably refute or corroborate these approaches (Thagaard et al. 2016). To this end, in order for future research work to accurately evaluate the evolutionary origins of ADHD, it is reasonable to assume that an integrated framework will be a more appropriate focal point as each of these leading approaches has seemingly only addressed one part of the equation. Under such an integrated framework, ADHD symptoms as a whole would conceivably have evolved gradually across different periods of human evolutionary history (e.g., when humans were mainly hunters or waders), or from a variety of different ancestral circumstances (e.g., when humans were required to be competent combatants during tribal warfare – even if they were actually not battling against the Neanderthals, to adapt to harsh and unpredictable conditions by reacting swiftly or be by being adventurous, or to have a small number of inquisitive members in a group who could provide valuable knowledge about environmental hazards).

Conclusion

Symptoms of ADHD have been posited by an assortment of approaches to confer survival benefits in the evolutionary past. These theories differentially suggested why such traits were advantageous for survival in the ancestral context, but are less useful in a modern world that is broadly dissimilar physically and socially to that of the former. Limited amount of empirical work has thus far evaluated the credibility of such approaches and more investigative research is hence undoubtedly needed in the literature. An integrative framework that combines all the heterogeneous explanations appears to be a more comprehensive and accurate account of the (prehistoric) survival advantages of ADHD traits.

Survival and Death

Bryan L. Koenig

Department of Psychology, Washington
University in St. Louis, St. Louis, MO, USA

Synonyms

[Living and dying](#); [Longevity](#); [Mortality](#); [Survivorship](#)

Definition

The continuation and cessation of being alive, respectively.

Introduction

The world of our ancestors abounded with dangers, from pathogens and predators to jealous lovers and war-minded out-groups. Such repeatedly encountered threats have exerted selective force that favored the evolution of adaptations specific to each type of threat. These adaptations enable continued survival in various ways, such as detection, avoidance, escape, or physical confrontation.

The degree to which an animal is well adapted to survive in its environment was the meaning of *fit* in “survival of the fittest” as used by Charles Darwin and his contemporaries (Darwin 1858/1968). A longer-necked giraffe was more fit in its environment than a shorter-necked giraffe if the longer neck enabled the giraffe to avoid starvation by eating hard-to-reach foods unavailable to its shorter-necked conspecific. Survival is obviously important during natural selection, because an organism has to be alive to reproduce, but biologists have come to realize that reproduction is often more important to natural selection than is survival. That is to say, natural selection favors animals reducing their likelihood of survival when doing so increases their reproductive output

(Williams 1957). Therefore *fitness* has been reconceptualized in terms of offspring produced. Natural selection at its most fundamental is about the propagation of genes into subsequent generations (Dawkins 1976). A key way to propagate genes is by having offspring, but it is not the only way. Considering fitness only in terms of offspring lacks recognition of the importance of helping the survival and reproduction of *genetic* relatives, who carry copies of the same genes. In modern evolutionary theory, the importance of survival and reproduction of genetic relatives is added to one's own reproduction, and together their effects on gene propagation are referred to as *inclusive fitness* (Hamilton 1964). In a sense, then, survival and death are about genes – but critically natural selection works at the level of individual organisms' phenotypes, which is where adaptations can be seen. We might therefore expect adaptations that lead individuals to trade off their own survival if doing so increases the survival of genetic relatives.

Survival – and its conclusion in death – has profound implications for the inclusive fitness of an organism. In most conceivable situations, survival enables – but death ends – the possibility of improving inclusive fitness. Survival and death are therefore central players in the process of natural selection and have been the focus of substantial research by evolutionary psychologists. Adaptations have been hypothesized to have evolved to solve a variety of problems, such as choosing a habitat, navigating the physical world, avoiding predators, avoiding pathogens and toxins, avoiding starvation and dehydration by consuming food and water, cooperating with kin and non-kin, permanently removing fitness threats via homicide, reaping substantial benefits for self and kin through warfare, and enhancing inclusive fitness by committing suicide. Evolutionary psychologists have also proposed explanations for aging and grief. Before considering specific adaptive problems, an overview of life and death in traditional societies provides the contexts that such adaptive problems arise in terms of how long humans naturally live and what dangers we faced at different ages.

Longevity and Causes of Death in Hunter-Gatherers

A cross-cultural review of available data on hunter-gatherers and forager-horticulturalists by Gurven and Kaplan (2007) provided a broad background regarding likely human longevity and causes of death in the environment of evolutionary adaptation. This is important because humans have spent most of our time as hunter-gatherers, and improvements in sanitation, nutrition, and public health have increased longevity in modern societies. For hunter-gatherers who lived to 15 years old, the most common age of death was 72 years, before which people tended to be productive and after which aging was severe. This finding led Gurven and Kaplan (2007) to suggest that “human bodies are designed to function well for about seven decades in the environment in which our species evolved” (p. 322).

Traditional societies vary somewhat regarding rates of mortality, especially mortality from warfare, but overall and compared to closely related species, the observed traditional societies were similar to one another (Gurven and Kaplan 2007). An average of 57 % of hunter-gatherers survived to age 15, and 64 % of those who lived to age 15 were also alive at age 45. Regarding life expectancy, those who survived to 5 years of age could expect to live on average to about 50 years old, those who survived to 15 years old could expect to live to about 55 years old, and those who survived to 45 could expect to live to about 65 years old. These findings indicate that aging (senescence) is not substantially greater in people who live in traditional societies as compared to those living in modern societies, but they reveal the greater number of threats to survival faced by people who live in traditional societies.

In their review, Gurven and Kaplan (2007) also summarized causes of death for people living in traditional societies (see Table 1). Overall, about 70 % of all deaths resulted from illness, 9 % from degenerative diseases, 6 % from warfare, 5 % from homicide, 8 % from accidents (e.g., falls, predation, drowning, burns), and 2 % from other causes. Illness was the major cause of deaths in

Survival and Death, Table 1 Percentages of death by their cause and by age class (summarized from Gurven and Kaplan 2007, p. 341, Table 5)

Cause of death	Age class			Total
	<15 years old	15–59 years old	60+ years old	
Illness	65.3	60.5	54.6	70.1
Degenerative disease	9.5	9.2	28.2	9.2
Accidents	8.1	12.9	10.3	8.1
Violence	17.1	17.4	6.9	12.5

adolescence and adulthood (60 % of deaths). For older adults, illness accounted for 55 % of deaths, degenerative diseases accounted for 28 %, and accidents for 10 %. For children, illness-related diarrhea compounded with malnutrition was especially deadly. Degenerative diseases were also dangerous for infants, accounting for 10 % of their deaths. Warfare, homicide, and accidents varied substantially across groups. Most homicides were infanticides, with homicide (inclusive of infanticide) accounting for 17 % of deaths before 15 years old. Across groups, accidents accounted for about 4 to 13 % of deaths. These rates were observed in contemporary traditional societies, so they might not perfectly reflect those in the ancestral environments in which humans evolved and lived. Gurven and Kaplan (2007) suggest that if systematic differences exist, most likely ancestral populations had less disease (due to greater social isolation) and higher mortality rates from homicide and warfare compared to the hunter-gatherers who have been observed by anthropologists.

The Nonhuman Environment

Habitat Navigation. Given the substantial impact of environmental dangers on survival in traditional societies, choice of habitat is important. The leading explanation for the evolution of human preferences regarding habitat selection is *The Savanna Theory* (Orians and Heerwagen, 1992). It argues that we evolved on the savanna, and therefore our preferences should match resource and danger distribution in that landscape. For example, people should prefer trees because they provided fruits, enabled predator avoidance,

and shaded us from the sun. We should also like plains, wherein large, huntable animals lived. A complementary approach is provided by *prospect-refuge theory* (Appleton 1988). It suggests that people should favor environments that enable the use of “prospect-providing” views, those that allow information gathering regarding such things as potential food or predators, and we should like “refuge-providing” views, those that allow hiding while observing the environment, such as is afforded by a clump of trees.

Another survival issue related to interacting with the physical world is addressed by Russel Jackson’s *evolved navigation theory* (Jackson and Willey 2013). This theory proposes that issues related to navigating the world – such as body-damaging falls from high cliffs, energy expenditure, and predation – have adapted the perceptual system so that it is biased in ways that reduce the likelihood of related mistakes. Such biases have been demonstrated in previously unknown perceptual illusions. For example, a vertical cliff appears longer when viewed from its top than its bottom, thereby enhancing caution at the top. Another example is that the distance toward a cliff edge appears longer than it is – suggesting extra metabolic costs that deter approach – whereas the same distance viewed from the cliff edge appears shorter than it is, enabling withdrawal.

Predators. In our evolutionary past, humans came into contact with predators such as large cats and hyenas (Barret, 2015). We were hunted by them and competed with them over kills. Predators and prey are special components of the environment because they are intentional agents that have adapted to us. Their relevant adaptations, such as cryptic coloration and intentional goals

to find or avoid humans, require specialized psychological mechanisms unlike those for dealing with static threats or opportunities, such as cliffs or ripe fruit. Adaptations that helped avoid predators include abilities to detect predators and predict their behavior (perhaps including “mindreading” abilities), memory and learning systems (such as prepared learning and social learning), and emotion and motivation systems (such as fear and anxiety; Barret 2015). Evidence suggests that even young humans are perceptually tuned to predator–prey interactions and born prepared to learn about potential predators such as snakes or objects that perceptually loom (appear to get closer). Adaptations for predator avoidance and food collection thus provide likely preadaptations for other adaptations, such as the ability to attribute goals and mental states to others (Barret 2015).

Pathogens, Parasites, Poisons, and Toxins.

As mentioned above, illness is the deadliest of the dangers faced by members of traditional societies (Gurven and Kaplan 2007), and so it is likely that selection has favored adaptations to avoid related costs. The emotion of *disgust* is believed to be an adaptation that evolved to help avoid microbes and other sources of disease (Rozin and Todd 2015). It shows many traits that fit with this proposal. It results in nausea and vomiting, which can remove dangerous substances from the body. It also motivates the avoidance and destruction of disgust-eliciting stimuli. Disgust is experienced less in men than women, which likely reflects the value of avoiding pathogens while women cared for and provided food for infants and children (Buss 2015). The heightened disgust of pregnant women is believed to help prevent women from consuming *teratogens* – agents that disrupt fetal development (Sherman and Flaxman 2001).

Evolutionary psychologists have argued that important features of culture are also related to pathogens. In addition to the physiological immune system, evolutionary psychologists argue that humans have a *behavioral immune system* that helps us avoid pathogens (Thornhill and Fincher 2014). The behavioral immune system helps people to avoid pathogens by avoiding and expressing prejudice against situations and

people that exhibit cues of the presence of disease, such as disfigurement or obesity. The behavioral immune system functions at the individual level, but groups of people are exposed to different levels of pathogens. For example, environments near the equator tend to harbor more pathogens and so groups that live there are exposed to more pathogens. Therefore groups are predicted to systematically vary in sociality variables related to pathogen avoidance depending on their degree of exposure to pathogens. More specifically, *parasite stress theory* argues that groups of people who live in areas with more pathogens should be more xenophobic, socially conservative, and exhibit other in-group biases – because these values enable people in those groups to avoid exposure to novel pathogens carried by out-group members (Thornhill and Fincher 2014).

Another way that groups differ is that spices are more commonly used in the cuisines of cultures that have higher levels of endemic pathogens (Sherman and Flaxman 2001). The *antimicrobial hypothesis* explains this pattern as a result of people capitalizing on the antibiotic effects of some spices to kill food-borne pathogens, which were especially likely to be a problem before refrigeration but are still a common danger today. Spices are molecules produced by a plant that are nonessential for the plant’s metabolism, instead having evolved to reduce the likelihood that the plant itself would be consumed by herbivores, bacteria, or other pathogens. Given that many people have an inborn dislike of spices and the culinary preference for spices is sometimes acquired – often through social pressure – it seems likely that the covariation of cultures and spices reflects cultural learning or cultural evolution. On the other hand, humans have inborn preferences for sweet foods (calorie-rich fruit evolved to entice consumers to eat it and spread seeds) and salt (a cellular-function essential) and dislike of bitter and sour foods, which are more likely to contain toxins and pathogens, and a fear of new and therefore potentially dangerous foods (Buss 2015).

Food and Water. Consuming water and appropriate food is a prerequisite for survival and the use of adaptations unrelated to water and food consumption (Tooby and DeVore 1987).

Humans are omnivores, so our ability to consume and digest a variety of foods helps us get the calories and nutrients we need. Being omnivorous also exposes humans to dangers of plant poisons and pathogens in animal tissues (Rozin and Todd 2015). Unique among animals, humans cook our food, aiding consumption and digestion while killing pathogens. Indeed, Richard Wrangham (2009) proposed that cooking food was a central development in the evolution of modern humans and our large brain. Food acquisition has a repeating pattern: hunger, search, capture, preparation, and consumption – with evolved adaptations for each phase (Rozin and Todd 2015).

Two key methods of searching for food are hunting and gathering. Human ancestors hunted regularly starting at least two million years ago, and over evolutionary time, hunting has been increasingly important (Barret 2015). Meat is a nutrient-rich food that provides a substantial proportion of the diet in many traditional societies (Buss 2015). Hunting almost always involves tools, some of which are projectiles that require substantial perceptual and motor skills (Barret 2015). Cross-generational teaching and learning is required for hunting-tool use. Possible adaptations to and consequences of the extreme complexity of human hunting and extractive foraging include growing larger, smarter brains, hunting and cooperating better, extending childhoods (to learn skills) and the overall length of the human life span (due to cross-generational resource sharing), and information-sharing abilities (Kaplan et al., 2000).

Tooby and DeVore (1987) proposed the *hunting hypothesis*, which claims that hunting large game resulted in the evolution of our large brain; home bases; enhanced human abilities for tool construction, tool use, communication, cooperation, and male coalitions; paternal investment in offspring and a resulting reduction in sexual dimorphism; social exchange; and the male–female division of labor. Kristen Hawkes (1991) proposed a largely complementary *show-off hypothesis*, which argues that big-game hunting – which occasionally provides highly nutritious food in such large windfalls that it is (often equitably) shared with others in the local group –

results in fitness benefits for hunters such as prestige, reciprocated food sharing and childcare, and increased sexual opportunities.

In contrast to the prior theories that suggest men’s hunting drove human evolution, Tanner and Zihlman (1976) suggested that women’s gathering played a key role. They argued that tool use developed for increased gathering efficiency, which is important given that in many traditional societies gathered foodstuffs provide the majority of calories and – unlike hunted animals – are a stable source of food. Regardless of its role in driving human evolution, foraging is likely to have selected for abilities related to spatial cognition, search assuming clumped resources, and the distribution of resources (Barret 2015). The ubiquitous division of labor in traditional societies with men hunting and women gathering is believed to have resulted in evolved sex differences in mental abilities, such as men’s tendency to navigate by direction whereas women use landmarks, men’s advantage on mental rotation tasks, and women’s advantage on object recognition and location recall (Buss 2015).

The Human Environment

Parental Investment in Hunter-Gatherer Societies. Human parent–offspring relationships in hunter-gatherer societies are exceptional in many ways. For example, our offspring are exceptionally dependent for a long time, and we address that dependency with parenting strategies unusual in the animal world (Apicella and Crittenden 2015). High mortality rates in children are common in hunter-gatherer societies, with morality rates of one-third to one-half of children dying before age 15 being common (see also Gurven and Kaplan 2007). Human babies are born so large-headed that childbirth is an extremely dangerous activity (Apicella and Crittenden 2015). The trade-off between extended gestational time and the head being larger (and more dangerous) at birth is believed to have resulted in human infants being born effectively as fetuses, with concomitant extended dependency. Human infants are weaned at a relatively young age, compared to

other primates, with an age of weaning about 1.5–2.5 years in hunter-gatherer societies. Human mothers have another child on average 3.5 years after the birth of their prior child, which is much shorter than other apes. Human adolescence is also extended compared to other primates. Explanations for the extended adolescence include that humans need time to learn how to survive in the local ecology or that it is a by-product of evolution of longer life. Human infants do not contribute resources to the group, but even children aged 3 years old in foraging societies contribute by helping in daily food collection. From 6 years of age through adolescence, immature humans can provide up to half of their own daily nutritional needs. Across infancy, childhood, and adolescence, developing humans require substantially more calories than could be provided by their mother alone (in hunter-gatherer societies). This problem is compounded because having multiple dependent offspring at the same time is common, although children help with caring for younger siblings.

Across hunter-gatherer societies, mothers provide the primary care for children, and in many societies fathers provide the second most care. Human males in most hunter-gatherer societies invest in their children, which is especially notable because paternal investment is exceptional among mammals. The degree of direct care, such as infant holding, by fathers varies substantially across hunter-gatherer societies, with the majority of paternal investment taking the form of provisioning. The high dependency of offspring, along with the necessary investment that is larger than the mother alone could provide, is thought to favor monogamy (one man with one woman) and serial monogamy (people forming a series of monogamous relationships) for most hunter-gatherers, with a minority of hunter-gatherer families with exceptional access to resources being polygynous (one man with multiple women). Parental care has been argued to be the reason men and women differ in their food collection specialization (i.e., hunting versus gathering). Hunted food, which comes in large but ancestrally unstorable packages, is often distributed to people outside the nuclear family, limiting the

provisioning of a father directly to his child. However, meat sharing might be unequal such that it disproportionately benefits the hunter's own family, while also enabling a man's child to benefit from successful hunts of other men. Father death has been found to reduce child survivorship in some but not all hunter-gatherer societies.

Cooperative Child-Rearing. Sarah Blaffer Hrdy (2009) argued that cooperative breeding – cooperative groups including nonrelatives providing for children – was a preadaptation that enabled the evolution of other human adaptations. Our ancestors suffered high mortality, especially when young, and young required substantial caloric provisioning but contributed little themselves. Given the high mortality rate of immature humans and mothers raising multiple immature children concurrently for which she alone would be unable to provide, help from others was a necessity. The infant, in turn, would need to read minds to request nurturing from its mother and others. “We have underestimated just how important shared care and provisioning of offspring by group members other than parents have been in shaping prosocial impulses” (p. 20). Hrdy (2009) argues that our empathy is based on child-rearing and that empathy in turn enabled our powerful culture. That is, we were emotionally modern before we evolved our large brains and language.

Within-Group Violence. Humans help raise one another's children, but they also have many conflicts of interest such that group members can be a hindrance rather than a boon to fitness. Joshua Duntley and David Buss proposed *homicide adaptation theory*, which argues that “homicide is the designed outcome of evolved psychological mechanisms” (Duntley 2015, p. 270). Adaptive problems posed by others in the social environment – such as threats to the self and family, having a reputation as being weak, or exposure to others who might exploit your resources – have the potential to be solved by homicide with a finality unlikely to come from causing injuries or signaling threats, which instead leave the competitor alive to cause the same type of problems in the future. Moreover, given that being murdered has long been an issue for humans, Duntley (2015) suggests that humans

have evolved complementary adaptations to avoid being killed, including avoiding situations where killing is likely, defenses against attackers, and ways of reducing death-related costs to relatives. These homicide-avoidance mechanisms, through a feedback system, further honed adaptations that produce homicides.

If people have evolved adaptations to kill others, then the patterns of homicides should make sense in light of evolutionary theory. This proposal was soundly supported by a review of homicide data by Martin Daly and Margo Wilson in their 1988 book, *Homicide*. The most common situation for murder is between “unrelated men, especially young men whose dismal prospects make dangerous escalation of social competition attractive” with a “cross-cultural universality of enormous sex differences in reproductive competition and same-sex homicide” (p. 294). That is to say, homicide is most common among young men because, of all demographic groups, they face the most intense competition with one another for access to resources and mates. Regarding murders within families, most are husbands killing spouses in attempts “to exert control over women and their reproductive capacities” (p. 295). This largely refers to men’s attempts to avoid being cuckolded – raising a child born of their wife that was fathered by another man – or having their mate abandon them. Analyzing ethnographic data of infanticide across cultures, Daly and Wilson found that infanticide occurs in circumstances “in which the child is of inappropriate paternity, is of poor phenotypic quality, or is unlikely to survive for other reasons” (p. 294). Other important factors include mothers being younger (and so having more time remaining in their life span to bear offspring), mothers being single (who have fewer resources, on average, than married mothers), children being young (with fewer resources having already been invested in them), and having a step-parent (who is genetically unrelated). That is, to say, infanticide is most likely when the offspring has an unusually low probability of successfully reaching maturity and competing for resources and mates. In short, the patterns of homicides in modern societies are explained within the framework of evolutionary psychology.

The demographic patterns of homicide victims that Daly and Wilson (1988) observed in modern society share notable consistencies with those reported by Gurven and Kaplan (2007) for traditional societies. In traditional societies with higher homicide rates, victims are disproportionately infants and children. Infanticide is most common in cases of twins, birth defects, perceived weakness, or ambiguous paternity – all situations where the offspring might either be especially burdensome or have a low chance of flourishing. Also, in societies with substantial adult homicide, the most common victims are adult males.

Warfare. Other groups afford dangers analogous to predators: they can sneak attack, ambush, or opportunistically aggress against lone individuals who are away from their group, so adaptations for avoiding predators likely served as preadaptations regarding intergroup conflict (Barret 2015). Like the concern of predators, warfare predates modern humans; it also occurs among chimpanzees and across resource-strapped human societies, from the modern to hunter-gatherers (Tooby and Cosmides 2010). John Tooby and Leda Cosmides (2010) explain warfare as an expression of a highly adapted coalitional psychology that is also reflected in politics, morality, and group psychology. Aggression, they argue, provides benefits by manipulating or eliminating people who are obstacles to increased fitness (e.g., they reside on better territory) or by enhancing bargaining outcomes (e.g., by threatening punishment for lack of compliance). The capacity to inflict costs on others – *formidability* – is greater for groups than individuals, so coalitions amplify the ability to eliminate fitness obstacles and to bargain. Coalitions provide many benefits and so might have been common across many species, but the evolution of coalitions has substantial barriers that have been overcome by few species other than humans. Humans had sufficient preadaptations: we lived with kin and so costs of coalition-member death were offset by inclusive-fitness benefits of related coalition members, we had advanced cognitive abilities such as theory of mind, and we had dangerous weapons that could kill from a distance. Also important was that coalition members could not predict which of them

would pay costs or reap benefits of coalitional warfare. Coalitional and warfare activities in turn drove further selection to hone cognitive and emotional adaptations for forming and maintaining coalitions as well as coordinating activities. For example, theory of mind was modified to perceive a group as if it had an individual mind – a phenomenon known as *entitativity*. Humans evolved adaptations allowing the formation of coalitions at various scales, with high-level coalition formation for conflict between groups being one of the most important due to “the prospect of large gains or huge losses through displacement, expropriation, subordination, or extermination” (p. 208). From this point of view, warfare is just one expression of our evolved adaptations for coalitional attempts to enhance individual fitness.

Other “Life-and-Death” Considerations

Aging. How natural selection could permit aging – the degradation of the body with increasing adult age – was a mystery until Peter Medawar (1952) and George Williams (1957) proposed two now commonly accepted mechanisms. Both mechanisms build on the observation that the strength of selection decreases with age, which in turn results from reduced survivorship over time. The first explanation – *mutation accumulation* – is that natural selection would be unable to eliminate harmful mutations that are expressed so late in life that most animals in wild populations would already have died. In safer environments, animals would live unnaturally long lives, and normally unexpressed genes would cause aging. The second explanation – *antagonistic pleiotropy* – is that natural selection would favor genes that have harmful effects later in life if they also had beneficial effects earlier in life. That is, a trade-off occurs between early-life vigor and reproduction at the cost of late-life survivorship.

Human aging has features that are anomalous given standard individual-selection models of evolution (Hamilton 1966). Most notably, human women lose the ability to reproduce due to menopause beginning at about 40 years of age, but can survive over twice that long. Standard

evolutionary theories would predict rapid aging and death during post-reproductive ages. One explanation for women’s post-reproductive survivorship is the *grandmother hypothesis* – the idea that women increase their inclusive fitness by helping their children and grandchildren to survive and reproduce (Hamilton 1966; Hawkes et al., 1998; Williams 1957). This is consistent with a review of hunter-gatherer societies that found about one-in-four persons in a traditional society would live as a grandparent for 15–20 years (Gurven and Kaplan 2007). In hunter-gatherer societies, grandmothers increase grandchild survivorship and growth and reduce mothers’ workloads (Hrdy 2009). Grandmothers sometimes selectively live in locations where her grandchildren’s father is absent or their daughters need more assistance. Grandmothers rank third, after mothers and fathers, in how much care they provide to children (Apicella and Crittenden 2015).

Another explanation for humans’ extended life span is provided by *embodied capital theory* (Gurven and Kaplan 2007). This theory suggests that humans need substantial time to physically develop and to learn how to hunt and gather during adolescence and that both men and women invest in educating their children and grandchildren (this theory is thus inclusive of, but more general than, the grandmother hypothesis). Productivity is low early in life but it increases across most of adulthood. This theory explains why the human life span evolved to end at about 60 years old: generally at that age, hunter-gatherer children and grandchildren are grown and no longer depend on the tutelage and provisioning of parents or grandparents. A potential caveat for the above theories of human aging was provided by Hill et al., (2007), who argued that for people to benefit from our extended longevity, people actually had to live longer first. They suggested that the initial extension of our life span was due to highly cooperative humans enabling others to survive by sharing food and caring for the sick and injured.

Grief. When a loved one dies, people react with extreme sadness. Arguing that this sadness is not merely a by-product of the attachment

system. Randolph Nesse (2005) proposed that grief is a special kind of sadness that was shaped, perhaps imperfectly, by natural selection. He notes some adaptive features of grief. It is elicited most strongly by the death of relatives, especially those at maximum reproductive value, and by the death of a close, personal relationship partner. When the body of the lost person is not present, grief induces a desire to search, which would have been adaptive ancestrally when someone was merely missing and not (yet) dead. Survivors ruminate about how the death might have been prevented, which could prevent similar losses in the future. The sadness and negative affect may play a role in disengaging from previous goals shared with the lost person that are no longer relevant, as well as pausing to consider how to move forward. Public displays of grief signal to others that one is capable of deep emotional relationships, which might lead others to choose the griever for cooperative endeavors.

Suicide. Denys de Catanzaro (1995) has provided the most thorough analysis of human suicide from an evolutionary perspective. He argues that there can be situations in which there is a trade-off between benefiting oneself versus harming one's kin (and so one's own genetic interests via inclusive fitness; Hamilton 1964). de Catanzaro argued that ψ , the "residual capacity to promote inclusive fitness," is a function of *reproductive value* (likelihood of producing offspring in the future) plus *kin solicitude*, the sum of possible current and future influences on the fitness of genetic relatives (1995, p. 386), with the latter weighted by Hamilton's coefficient of relatedness. Young, healthy individuals would have high ψ values because their reproductive potential would be high, as would their potential to aid relatives. In post-reproductive individuals, ψ could be positive if aiding kin is possible. Critically, for individuals with low or zero reproductive value, being burdensome to relatives could result in kin solicitude being negative, potentially enough to offset any remaining reproductive value, resulting in a negative value for ψ . This would mean the person is costly to his or her own inclusive fitness. When such situations arise, de Catanzaro argues that self-destructive adaptations

might be expressed, such as physiological failures and self-harming, including suicide. Consistent with this proposition, suicide is higher among older individuals, men, people who fail to acquire a romantic partner, the chronically ill, the disgraced, the socially isolated, and those who experience failure. Moreover, suicide ideation positively correlated with perceived burden on family, as did lack of social connections (loneliness) in elders, whereas sexual activity was negatively related to suicide ideation in younger adults.

Conclusion

The evolution of humans has involved the development of adaptations to help avoid death and thereby continue the survival of oneself, one's kin, and one's coalition members. For over a decade at the start of our lives, humans depend on parents and other group members for food and protection from numerous threats. Once we become mature, we face additional dangers related to mating and coalition-related competition within and between groups. We help one another survive to a degree that is extreme in nature, but we also use deadly force to a likewise extreme degree.

Symbiotic and mutualistic relationships

Definitions

Symbiosis refers to a close and prolonged association between two organisms of different species. Mutualism refers to mutually beneficial interactions between members of the same or different species. Mutualistic interactions need not necessarily be symbiotic.

Introduction

Symbiotic and mutualistic interactions are important in evolution because they constitute types of interactions between organisms that affect their fitness. These types of interactions and relationships may assume many forms. An increasing number of investigators have suggested that the prevalence and significance of mutualism have been underestimated in research on cooperation (Dugatkin 1997). Accounting for the evolution of mutualism is challenging, because it often is difficult to quantify the short-term and long-term, direct and indirect, costs and benefits of mutual exchanges and to explain how cooperating organisms avoid exploiter and free-rider problems.

Types of Symbiosis

Symbiotic interactions are commonly classified as parasitism, commensalism, amensalism, or

mutualism. In parasitism, one organism in the association benefits while the other is harmed (+ −). An example is a flea feeding off its host. In commensalism, one organism in the association benefits while the other is neither helped nor harmed (+0). For example, spiders benefit from building webs on plants while plants remain unharmed. Amensalism occurs when one organism harms another but is neither harmed nor benefitted as a result (−0), for example, cows crushing grass as they walk. Mutualism occurs when both organisms in an association benefit (+ +).

Mutualism

Mutualism may occur in dyadic or multiindividual interactions. A classic example of mutualism is cleaning symbiosis in fish and shrimp. One species – the cleaner – cleans another species – the client – by removing parasites, often entering into the mouth of the client to perform this service. The cleaner reaps a benefit by obtaining food; the client reaps a benefit by getting cleaned. In certain conditions, such as when the costs of parasite affliction are high, when the supply of cleaner fish is low, and when cleaners and clients form an ongoing symbiotic relationship, the benefits of getting cleaned outweigh the benefits of eating the cleaner fish.

Types of Mutualism

Investigators have distinguished between obligate and facultative mutualism. In obligate mutualism, two organisms in a mutualistic association are dependent on each other for survival. In facultative mutualism, two organisms benefit from each other but are not dependent on their mutualistic association for survival.

Bergstrom et al. (2003) have identified four forms of mutualism that have been extensively studied by biologists:

Protection mutualisms: protection from a third species traded for food (e.g., cleaning)

Transportation mutualisms: food traded for transport of organism or gametes (e.g., pollination)

Nutrition mutualisms: food traded for food or protection, usually symbiotic (e.g., plant-mycorrhizal symbiosis)

Shared benefit mutualisms: aggregations of many species obtaining benefits from shared vigilance or defense (e.g., mixed-species foraging)

Bergstrom et al. (2003) also have offered a classification of the key variables that differ across types of mutualism. These variables include: (a) magnitude of benefits, (b) magnitude of investment, (c) cost of being cheated, (d) potential for sanction, (e) obligacy, (f) specificity, (g) opportunity for choice, (h) population structure, (i) symmetry, (j) duration of association, (k) influence of third parties, and (l) evolutionary rate.

Intraspecies Mutualism

In evolutionary biology and evolutionary psychology, the term “mutualism” has been used to refer to behaviors that benefit two or more members of the same species (Bornstein 2003, pp. 186–187). Some theorists have questioned this use of the term (West et al. 2007), suggesting that the term “mutual benefit” is more appropriate for intraspecies forms of mutualism. Common examples of intraspecies mutualism, or mutual benefit, include group hunting, group defense, coalitions, cooperative breeding, and communal nursing (van Schaik et al. 2006).

Several evolutionary theorists have concluded that mutualism is more prevalent in the animal kingdom than previously assumed: “Mutualism may be the most prevalent form of cooperation; it occurs frequently across a wide variety of taxa” (Stevens et al. 2005); “A growing number of studies show that mutualism has been underestimated because the costs of participating in the cooperative act have been overestimated and the direct benefits of cooperation have probably been underestimated. . .” (Boesch et al. 2006, p. 149).

Synergistic and By-Product Mutualism

Biologists also have drawn a distinction between by-product mutualism and synergistic mutualism. In by-product mutualism, interacting individuals benefit each other incidentally as a by-product of individually selfish (fitness-increasing) behaviors. Examples include groups of individuals clustering together to reduce chances of predation and escape behavior that alerts other group members of danger. In synergistic mutualism, individuals work together or join forces to produce benefits for themselves and their partners. Examples include coalitions and coordinated forms of group hunting and defense.

In contrast to by-product mutualism, for which no special adaptations may be necessary, in synergistic forms of mutualism, individuals may need to acquire adaptations that enable them to coordinate their efforts to maximize their gains. For example, when dolphins engage in group hunting, they implement a division of labor in which one member of the group chases a prey toward other members of the group. Although there has not been much research on adaptations for coordination, such adaptations probably played a significant role in the evolution of the human species.

Mutualism, Reciprocity, and Pseudoreciprocity

It is commonly assumed that mutualism differs from reciprocity because the benefits of mutualism are immediate, whereas the benefits of reciprocity to one partner are delayed (van Schaik and Kappeler 2006, p. 6) – “you scratch my back, *then* I will scratch your back.” However, in simultaneous forms of reciprocity, individuals may exchange goods or services by, in effect, scratching one another’s backs simultaneously or giving with one hand and taking with the other. The essential difference between reciprocity and mutualism is that in reciprocal exchanges the behaviors that benefit recipients are costly to donors, whereas in mutualism, the behaviors that benefit recipients are also beneficial to donors. Several investigators have suggested that many

acts classified as reciprocity may actually constitute incidents of by-product mutualism or pseudo-reciprocity. Pseudoreciprocity occurs when one individual or organism invests in another individual or organism that produces by-products of benefit to the investor. For example, a bird fertilizes a bush that grows tall enough to shade its nest. “The bird’s return benefit is an incidental effect or by-product of a self-promoting act (growth) on the part of the bush” (Leimar and Connor 2003, p. 205).

The Evolution of Mutualism

Mutualism can evolve when the benefits experienced by two or more individuals interacting with one another exceed the benefits of not interacting or defecting. The benefits could be direct (e.g., increased probability of killing prey, improved defense against predators, increased rank, increased access to mates) or indirect (e.g., improved reproductive success of kin).

Theorists such as Scheel and Packer (1991) have suggested that mutualism usually evolves in hostile environments in which two or more individuals are needed to solve survival or reproductive problems. Familiar examples include group defense in humans and other primates, huddling together in penguins, and group hunting and coalitions in humans and chimpanzees. There probably were strong selective pressures for intra-species mutualism in the human species. Early humans lived in hostile environments containing predators (including other humans) and large game. In contrast to other species, in which dyadic mutualism is most common, humans engage in vast amounts of group-level mutualism.

As with other forms of cooperation, cheating, exploitation, and free-riding are obstacles to the evolution of mutualism. It is in each individual’s interest to minimize his or her costs and maximize his or her benefits from mutually beneficial interactions and relationships; however, if one or more participants adopt this strategy, they could fail to produce the resources they need. A related obstacle to the evolution of mutualism is risk avoidance in collaborative activities, such as group hunting

of dangerous prey, group defense, and agonistic coalitions, in which cheaters attempt to avoid the costs of dangerous injuries. To evolve, adaptations for mutualism must be designed in ways that either prevent exploitation and free-riding or ensure that cheaters do not evolve in greater numbers than cooperators do. When two animals have an ongoing exclusive symbiotic relationship, exploiting their partners in ways that reduce their partners’ chances of surviving may be very costly (Bornstein 2003). A common way of guarding against being cheated – in humans and such other animals as cleaner fish – is to reject those who fail to contribute adequately to mutual tasks and replace them with other partners. Other safeguards include reducing the costs of being exploited, avoiding those with a reputation for cheating, forcing cheaters to cooperate, and punishing cheaters in a variety of ways.

Conclusion

Members of many species form symbiotic and mutualistic relationships, and these relationships may assume several different forms. Although the term mutualism originally was invoked to describe a form of cooperation between members of different species, it also has been applied to certain forms of cooperation within species. In by-product forms of mutualism, animals benefit one another incidentally; whereas in synergetic forms of mutualism, animals coordinate their efforts to obtain the benefits they share. Mutualism is sometimes confused with reciprocity and pseudoreciprocity, but it differs in significant ways. Cheating and free-riding may constitute significant obstacles to the evolution of mutualism.

Definitions

The creation, use, and transfer of symbolic objects, such as the creation of meaningful images and soundscapes, through culturally mediated transmission.

Introduction

Discerning what makes *Homo sapiens* unique among the rest of the species on the planet has been a difficult task, especially as behaviors such as tool use, learning, altruism, and compassion have been reported in nonhuman animals (though not without controversy). What does seem distinctive is our unique symbolic culture, the use and transmission of symbols inter-generationally. To be clear, animals use sound for communication, and some have elaborate systems of information transfer, but only modern humans use symbolic culture to create and recreate the human niche through concepts such as good and evil and political systems. The origin of symbolic culture has been a major research topic for scholars studying human evolution and has been the subject of contentious debate as to when and where it evolved, as well as what makes something symbolic.

Semiosis

The specific meaning a symbol has is bestowed on it by humans. This meaning can only be ascertained by symbolic communication. For this

reason, it is often seen as a marker of modern human origins and a signal as to the use of language. The American anthropologist Leslie White argues that “Human behavior is symbolic behavior; symbolic behavior is human behavior” (White 1940, p. 451). However, what exactly a symbol is has been the subject of intense debate in both anthropology and semiotics, the study of signs. The two key thinkers on this subject are Ferdinand de Saussure (1857–1913) and Charles Peirce (1839–1914). A key difference in the two approaches is that Saussure’s theory was developed to understand linguistic signs, while Peirce saw linguistic signs as part of a more general system. From an evolutionary standpoint, Peirce’s model provides a more nuanced, though more complex, approach (Kissel and Fuentes 2016).

For subscribers of Peircean semiotics, symbols are signs that only stand for their objects due to conventional agreement as to their meaning. For example, the only reason that a red light means “stop” is that everyone agrees that is the meaning, rather than it being linked by causation (such as a weather vane indicating the wind direction) or similarity (a picture of a bicycle stands for that object). Many anthropologists have argued that only humans use symbols (Deacon 1997). Thus, symbolic culture should only be found in *Homo sapiens*. If true, tracking the evolution of symbolic thought allows scientists to better understand how hominins became human.

Evolution of Symbolic Thought

The earliest members of the genus *Homo* date to over 2 million years old, but many of the early examples of this species do not resemble modern humans. Paleontologists have uncovered remains of *H. sapiens* dating to around 195,000 years ago in Eastern Africa, suggesting that anatomically modern humans date to at least this time period. The fossil record is mute on the question of when hominins began to act modern, however. Notably, many researchers suggest there was a time lag between anatomical modernity and behavioral modernity, the so-called sapiens paradox (Renfrew 1996). Recent work has suggested that this paradox is a product of research bias and

preservation issues (McBrearty and Brooks 2000; Shea 2011), while some suggest that these behaviors have their origins before the evolution of modern humans (Bednarik 2008).

Recently, archeologists have concentrated on the material record in the hopes of delineating when and where our ancestors developed the capacity to think symbolically. Various classes of archeological data such as beads made of shell, bone, or stone; the use of ochre as a body decoration or adhesive; engravings on bone, stone, and ochre; hafting and blade technology; bone tools; artwork; the use of exotic materials; and intentional burial have been used to indicate human cognitive advances. How exactly these artifacts indicate symbolic thought has been the subject of much theorizing, and debate remains as to whether these artifacts indicate symbolic thought. Beads, for example, may suggest that the wearer wanted to signal to other’s who they were and where they come from.

One site that has received much attention is Blombos Cave on the Western Cape of South Africa (Henshilwood et al. 2002). The site has preserved remarkable examples of early symbolic expression, such as shell beads and bone tools at ~73,000 years ago and an ochre processing workshop dating to ~100,000 years ago. While Blombos is one of the best-supported sites indicating contemporary capacity for symbolic thought, other earlier examples exist. For example, scientists working with collections from Java, Indonesia, report engraved lines on a clam shell from a 380,000-year-old site associated with *Homo erectus*. Moreover, ochre use is reported at a 200,000-year-old Neanderthal site. Interestingly, the recently described species *Homo naledi*, with a brain size ~40% that of modern humans, may have had an advanced mortuary practice normally believed to only be seen in anatomically modern humans (Berger et al. 2015). This and other finds may indicate that symbolic originated earlier than has previously been suggested.

Conclusions

The relevance of this is that symbolic thought is suggested to be the basis for language and shared

intentionality, which in turn allows for cumulative cultural learning. Humans create, remake, and modify their cultural niche through symbolic thought and intergenerational learning. Furthermore, evidence from Blombos of shifting styles of bead wearing may indicate the use of full-fledged language. If symbolic thought is a prerequisite for language, its archeological indicators can pinpoint the origins of this uniquely human ability. Humans' remarkable evolutionary success can in part be traced to this ability to share and store information extrasomatically. While research has often focused on the role symbolic thought played in the origins of human language, this often overlooks other aspects of symbolic culture, such as the creation of the human ability to create and innovate (Fuentes 2017). This symbolic niche, one which seems to only be occupied by modern humans, is both the result of, and the cause for, human's remarkable evolutionary success. It allowed our ancestors to start as a relatively small population 200,000 years ago and become the cosmopolitan species we are today.

Telling stories around the campfire allows others to share not just subsistence practices but gossip, ideas, thoughts, and cultural knowledge. The power in symbolic culture is that it allows this data transfer to occur with high fidelity. By at least 300,000 years ago, we can see the initial glimmers of these behaviors as human populations experimented with different ways to express themselves. What seems clear is that humans have been experimenting with meaning-making since before *Homo sapiens* evolved. Even the simplest stone tools could, in theory, be imbued with meaning. The challenge is in understanding how humans were able to create these meanings.

Tactics to Solve Adaptive Problems of Sperm Competition

Rebecca L. Burch¹ and Gordon G. Gallup²

¹State University of New York at Oswego,
Oswego, NY, USA

²State University of New York at Albany, Albany,
NY, USA

Definition

The ways in which males strategize to maximize their reproductive fitness in a competitive mating context.

Introduction

Males of all sexually reproducing species compete among one another for paternity. For most males in such species, insemination is usually the end point in the reproductive process; most males do not provision and/or care for their offspring.

Paternal Assurance Tactics

However, in species where the offspring are particularly helpless at birth and require protection and provisioning from both parents (which includes some tree nesting birds and a few primates) the possibility of being cuckolded (i.e., duped into caring for offspring sired by other males) adds to the costs of nonpaternity. Human's anchor this latter dimension. Human infants are more helpless at birth and remain parent dependent for longer periods of time than those of any other species. As a consequence, evolution has operated to produce an ensemble of paternal assurance tactics among human males which function to minimize the chances of being cuckolded. Gallup and Burch (2006) have identified four sequentially dependent strategies that men use (wittingly or not) to increase the chances that they share genes in common with their ostensible children. These include *Insemination Prevention Tactics*, which include mate guarding, mate sequestering, mate monitoring, and male sexual jealousy that function to minimize insemination by rival males. If these tactics fail and a female is inseminated by another male, men move to *Counter Insemination Tactics* which function to reduce the chances of conception as a consequence of insemination by other men, such as sperm competition. Should conception occur as a byproduct of having sex with other men, the ground rules change and men resort to *Pregnancy*

Termination Tactics, and in the event of a live birth men shift to *Postpartum Investment Tactics* where investment in children varies in relationship to the proportion of shared genes between the resident male and the child.

Sperm competition is commonly featured in many diverse species as a means of competing for paternity. This can include context specific adjustments to the ejaculate in terms of the number of sperm which take into account the likelihood of insemination by other males. In some species, most notably humans, there also appear to have been mechanical/morphological adaptations to penis morphology which function to displace rival male sperm from the female's reproductive tract and enable the resident male to substitute his sperm for those of his rivals (Gallup et al. 2003).

Conclusion

The evolution of the glans and the coronal ridge at the end of the penis and the resulting semen displacement properties of the human penis have also led to selective pressure for the size of the penis. That is, confronted with the prospect of semen displacement from rival males there was probably selective pressure for longer penises to deposit semen in the least accessible parts of the vagina to minimize displacement. However, that in turn would up the ante for an even longer penis to access and displace semen from the most remote parts of the vagina, creating an evolutionary arms race of sorts. Thus, both the shape/configuration of the penis and the size of the penis in humans appear to have evolved to capitalize on semen displacement as another sperm competition strategy.

Tactics Versus Strategies

William Felton and Brian Pugliese
University of Idaho, Moscow, ID, USA

Definition

Strategy refers to a set of behavioral adaptations while *tactics* are the individual actions taken to pursue a strategy (Gangestad and Simpson 2000).

Introduction

In the context of evolutionary behavior, *strategy* refers to a set of adaptations that determine the range of behaviors that an organism may employ (i.e., to fight, flee, or hide). *Tactic* refers to the specific behavior used within that organism's pre-set strategy; for example, fighting or retreating in the face of competitor conflict (Dawkins 1999). The two terms are closely related, often used in conjunction while discussing conflict related to intrasexual and intersexual selection of mates (Taborsky et al. 2008).

Strategies and Tactics

The distinction between strategy and tactic in terms of behavioral ecology can be, at times, ambiguous and difficult to grasp. Various authors (Dawkins 1999; Dominey 1984; Taborsky et al. 2008) have

acknowledged the potential to confuse the terms with one another. In an attempt to limit confusion, Dawkins (1999) prefers to use the word “program” instead of “strategy.” When considering strategy as it relates to behavioral ecology, it may be useful to use Dawkins’ (1999) analogy and conceptualize strategy as a computer program. A code creates a computer program in order to perform a single action within a set of potential actions.

The unseen code programs the set of available responses. In this example, the code and responses are analogous to strategy and tactics, respectively.

While strategy in general refers to rules governing a set of tactics, there is a further sub-categorization of their relationship.

The most basic categorization being a *pure strategy*, in which the strategy determines a single tactic to be used without any alternative (Neff and Svensson 2013). An example of a pure strategy is an organism, when faced with competitors during mating, only has the behavioral tactic to fight, with no alternative tactic available. A further example is Maynard’s (1976) explanation, which uses the game of rock-paper-scissors as an analogy. A pure strategy, in the game of rock-paper-scissors, would be always employing rock, without ever considering or using the two alternative choices.

A *mixed strategy* can employ more than one tactic, such as to fight or to flee when faced with a competitor (Neff and Svensson 2013). A mixed strategy for a given goal applies a tactic based on preset probabilities defined by its genotype, such as choosing to fight in 70% of encounters and choosing to flee in 30% of encounters (Dominey 1984). Alternatively, mixed strategies may be probabilistically assigned a given tactic for their entire lifetime, such as 70% of the species always opting to fight and 30% always opting to flee when facing a competitor (Dominey 1984).

Neither a pure strategy nor a mixed strategy considers aspects of the organism’s environment and conditions as a determinant of an employed tactic. A *conditional strategy* is one in which the tactic used provides the highest chance of reproduction given the context and surroundings of the situation (Neff and Svensson 2013). A key

difference with conditional strategies is the active decision making by the organism given the context, rather than the use of a single behavioral option or probabilistic behavioral option (Gross 1996). An example of conditional strategy is an individual, when faced with a competitor, chooses to fight if larger, but flee if smaller, than the competitor. In other words, the individual decides on tactic based on the current condition. Behavioral ecologists often consider conditional strategies as superior for their ability to fit the changing demands of the environment (Plaistow et al. 2004).

An important note is that an individual’s strategy is goal specific and not species specific. For example, the same individual may have a pure strategy for fighting competitors, a mixed strategy for foraging, and a conditional strategy for attracting a mate.

Conclusion

Though the terms strategy and tactic can be confusing, their distinction is an important one to make in behavioral ecology. The terminology provides a hierarchical framework to understand an organism’s specific behavior – its tactic – as an option within a larger set of adapted behaviors – its strategy. Additionally, the distinction between strategy and tactic is important to the discussion of many related topics, such as behavioral adaptation, sexual selection, evolutionary game theory, and others (Dominey 1984; Smith 1976; Taborsky et al. 2008). A basic understanding of the two terms, and their relationship to one another, provides a fuller understanding of behavioral ecology and several subsections of theory within.

Talking About Others

► Social Consequences of Initiating Gossip

Tall Poppy

Marie T. Dasborough
University of Miami, Coral Gables, FL, USA

Synonyms

High achiever; High status individual; Top dog

Definition

The term “tall poppy” refers to a person of high status, elevated above their peers due to their achievement of fortune or fame and/or high levels of achievement.

Introduction

Their higher social position of “tall poppies” differentiates them from others within the social context. This label of “tall poppy” has a negative connotation and is largely used in a derogatory manner in Australia, in New Zealand, and to a lesser extent in the UK.

Tall Poppy Syndrome

The “tall poppy syndrome” refers to the social phenomenon of the desire to cut down such tall poppies (Feather 1989). This is closely tied with the egalitarian values of Australia where there is a belief that no Australian should assume that she/he is any better than other (Peeters 2004). Everyone in society should be of equal status, so the desire to cut down the tall poppy is in fact a desire to level the playing field.

The key scholar in the field of “tall poppies” is Norman Feather, an Emeritus Professor at Flinders University in South Australia. He has examined perceived deservingness and the emotions of envy and resentment, as predictors of whether a “tall poppy” will be cut down to size. When a tall poppy is perceived to be undeserving of their higher status, for example, becoming famous without any real talent, individuals have a greater desire for this type of tall poppy to be cut down (Feather 2012). Strong feelings of jealousy, hostile envy (not benign envy), and resentment are also predictors of the desire to cut down a tall poppy. Benign envy is not associated with desire to cut down a tall poppy, but instead it is viewed as a motivational force that can drive others to improve themselves.

Building on this foundation, Feather has also examined emotional responses to when tall poppies do in fact fall. Some observers will feel sympathy, while others will feel schadenfreude (joy at another person’s misfortune). The specific type of emotion experienced will depend on the type of fall and the perceived deservingness of that fall (Feather 2012). For example, research by Dasborough and Harvey (2017) has shown that individuals feel more schadenfreude in response to a tall poppy being cut down if that

tall poppy was perceived to be unethical while holding the tall poppy status.

Tall poppies have been studied within the context of student academic performance, scholarly contributions by academics, athletic performance, sports teams, employees, entrepreneurs, and politicians (e. g. Feather 1989; 1991; 1994; 2012; Feather and McKee 2014; Feather et al. 1991; Kirkwood 2007). It is more likely in competitive scenarios, where individuals perceive success and high status to be a zero-sum game. Since status is a relative value; for an individual to boost their own social status, it is perceived that another individual must be lower in status. This desire to cut down tall poppies has also been connected to the “queen bee syndrome,” where women undermine the success of other tall poppy women in workplaces (Funk 2004).

Conclusion

The tall poppy syndrome has been seen in various countries, and across a range of contexts. Given that this syndrome may discourage over-achievers, it is something to be aware of. After all, we are more successful if we build up our high achievers and celebrate them, rather than cut these tall poppies down.

Definition

The chemosensory system registering the presence of specific molecules in food ingested by humans and other animals.

Introduction

Although humans experience a large number of sensations when consuming food, much of the

enjoyment of food comes from a combination of smell and taste. Technically, taste is derived from receptors on the tongue and on the epiglottis and a few other places within the mouth. Humans appear to be sensitive to four basic tastes including sweet, salty, sour, and bitter. These basic tastes have been identified by their seemingly adaptive purpose and the hard coding that appears to exist for these tastes. More recently, another basic taste has been proposed. This newer taste category is known as umami and can be thought of as “savory.” This is the taste associated with glutamate, which comes from proteins in meat. Including umami as a basic taste is still somewhat controversial, but receptors for glutamate have been found in the gut and digestive tract. The basic tastes appear to have an important function in terms of the ingestion of nutrients and the avoidance of toxic substances. Sweet tastes indicate the presence of glucose, an important source of energy and something vital to survival. Bitter tastes also serve an important adaptive purpose in that the bitter taste signals the presence of potential toxins in food, allowing us to avoid ingesting harmful or toxic substances. The value of the other two tastes are not as clear with sour potentially also allowing for some protection by signaling the presence of acid. The sour taste is associated with weak acids that are not harmful, but the same taste is also associated with stronger acids that could potentially prove harmful. Again, the sour taste could be protective by allowing the rejection of the material before it is ingested. The taste of saltiness also signals an ion important in many biological functions, so being sensitive to the taste of salt would be beneficial and have survival value as well.

Given the survival value of the basic tastes, it is not surprising that we have developed highly sophisticated and specialized receptors for these stimuli. The taste receptor cells are located within taste buds, which are found in small bumps on the tongue and other structures within the mouth and digestive system called papillae. There are four types of papillae on the tongue, including the filiform, fungiform, foliate, and circumvallate papillae. Only the fungiform, foliate, and circumvallate papillae contain taste buds and taste

receptor cells. Of these, the fungiform papillae, so named because of their mushroom shape, are the most numerous and are found in the lateral portions of the anterior two-thirds of the tongue. These papillae contain one or more taste buds per papilla (Smith and Margolskee 2001) with each taste bud containing between 50 and 100 taste receptor cells (Chaudhari and Roper 2010; Roper 2013). The foliate papillae are found on the lateral edge of the tongue at the back of the tongue immediately anterior to the vallate line. The circumvallate papillae are large structures found at the back of the tongue in an inverted “v” shape. In humans, there are between 3 and 13 of these papillae per tongue with between 700 and 3000 taste buds found in the circumvallate papillae (Spielman and Brand 1995).

The taste receptor cells are found in taste buds in an orange-like arrangement of receptor cells. They send tiny projections, called microvilli, through the pore found at the top of each taste bud where they contact the molecules from the tastants that have been dissolved in saliva through the chewing and eating process.

Cells Found in Taste Buds

Chaudhari and Roper (2010) reviewed recent findings on the various cells in each taste bud. They indicate that there are three cells consistently identified that are associated with taste transduction including Type I, Type II, and Type III cells. Although Type I cells are the most abundant, they are also the cells we know the least about (Chaudhari and Roper 2010). They appear to have “extended cytoplasmic lamellae that engulf other cells” (Chaudhari and Roper 2010, p. 288) and serve a function similar to glial cells in the central nervous system. Specifically, Type I cells appear to help terminate synaptic transmission and inhibit the spread of neurotransmitters (Chaudhari and Roper 2010). They have been linked to salty taste transduction via the direct entry of Na⁺ ions through open ionic gates. Type II cells are also referred to as receptor cells, and these cells appear to respond to sweet, bitter, and umami tastants, but are insensitive to sour and

salty tastes (Chaudhari and Roper 2010). These cells are specialized with different cells detecting specific tastes when molecules in the tastants dock on receptor sites (known as G-protein-coupled receptors or GPCRs) on the receptor cell microvilli causing a cascade of activity within the cell resulting in a release of internally stored calcium ions which then cause a release of the neurotransmitter adenosine triphosphate (ATP). ATP then causes action potentials in the sensory neuron closest to the cells. These signals are then sent to higher levels of the brain where they are then interpreted as specific tastes. Interestingly, these receptor cells (Type II) do not make synaptic contact with neurons sending signals to the brain by way of vesicles releasing neurotransmitters. Instead, the resulting release of ATP triggers action potential generation in the neurons communicating with higher levels of the brain. The Type III cells are also known as presynaptic cells. They express proteins associated with synapses and form synaptic junctions with closely associated nerve terminals (Chaudhari and Roper 2010). These cells may play a role in the responses of other cells and send signals from receptor cells to higher levels of the processing system. They also respond directly to sour tastes and indirectly to sweet, bitter, and umami tastes via the neurotransmitter ATP (Chaudhari and Roper 2010). The presynaptic cell also plays an important role in the receiving and integration of information from receptor cells. Thus, unlike the receptor cells, these cells are not finely tuned and respond to a large variety of taste stimuli (Chaudhari and Roper 2010).

Transmission of Signals from Receptors to the Brain

The signals received on the tongue are sent to the brain through three cranial nerves (cranial nerves VII, IX, and X). Specifically, the anterior 2/3 of the tongue is innervated by the chorda tympani branch of the facial nerve (the VIIth cranial nerve). The posterior 1/3 of the tongue is innervated by the glossopharyngeal nerve (cranial nerve IX), while the taste buds found in the soft

palate and the taste buds at the back of the mouth are innervated by the vagus nerve (cranial nerve X). All of these nerves send impulses to the nucleus of the solitary tract of the pons and medulla. From there, the signals travel to the thalamus, where they synapse once more. Then projections go to the primary taste cortex (the insula) and then to the orbitofrontal cortex of the frontal lobe.

Originally, researcher believed that the taste system would show the same specificity of processing found in the visual system and have specific receptors connecting with specific neuronal channels resulting in the perception of specific tastes. This hypothesis was known as the labeled lines hypothesis. However, researchers now believe that the activity in the brain is of a more general nature and is not specific to the different tastes. Researchers now agree that it is the interpretation of a pattern of activation from a variety of taste receptor cells that result in the specific taste being perceived (Chaudhari and Roper 2010; Scott and Giza 2000; Smith et al. 2000).

Genetic Variations in Taste Perception

Researchers (e.g., Bartoshuk 2000; Prutkin et al. 2000) have indicated that individuals have different taste experiences due to both gender and other genetic influences. In particular, there is individual variation in terms of sensitivity to the bitter taste of PROP (6-n-propylthiouracil), which is a thyroid medication, but in low doses serves as a stimulus in taste experiments. Prutkin et al. report that approximately 25% of the population have no ability to taste the bitterness of PROP. An additional 50% of the population experience the taste of PROP as bitter, while the final 25% of the population experience the taste of PROP as extremely bitter. Those who do not experience a bitter taste when tasting PROP are labeled as “nontasters.” Those who perceive bitterness when tasting PROP are labeled as “tasters,” and those who experience PROP as tasting extremely bitter are “supertasters.” The population distribution for the bitter taste of PROP has been linked to genetics, with the ability to taste PROP linked to a

specific recessive gene (Bartoshuk 2000). According to Bartoshuk (2000), supertasters possess both alleles for this tasting gene, while tasters have received only one allele. Nontasters have not received either allele for this tasting gene. Furthermore, Prutkin et al. indicate that the physical manifestation of this genetic difference is found in the number of fungiform papillae on the tongue of supertasters, tasters, and nontasters. Specifically, supertasters have the most fungiform papillae, while nontasters have the fewest, and tasters have a number between these two extremes.

There are many behavioral consequences and outcomes to these genetic differences in the number of fungiform papillae that have been discovered. Supertasters, for instance, tend to experience a unique taste world and have extreme taste sensations on a number of fronts (Prutkin et al. 2000). According to Prutkin et al. (2000), supertasters tend to experience the bitter tastes of many vegetables to a higher degree than tasters and nontasters, so they may avoid eating vegetables, leading to a diet lower in fiber than may be healthy. This may lead to health problems, and supertasters have been found to have a higher incidence of colorectal cancer (Prutkin et al. 2000).

Women are more likely than men to be supertasters and that taste sensitivity varies with hormonal levels with peaks and troughs at various points in the menstrual cycle that tend to differ for different women (Prutkin et al. 2000). In addition, sensitivity to bitter taste also varies over the course of pregnancy with the highest sensitivity in the first trimester, when major organs are forming and when exposure to teratogens may have the largest effect. In effect, this variation in sensitivity to bitter makes the woman in her first trimester of pregnancy the most effective poison detector (Prutkin et al. 2000). Additionally, sensitivity to bitter appears to outlast pregnancy with fewer nontasters among women who have had at least one child than those with no children (Prutkin et al. 2000). Finally, sensitivity to bitter taste appears to diminish after menopause when women are past their childbearing years (Prutkin et al. 2000).

Conclusions

In summary, human taste sensitivity includes four (and possibly more) basic tastes, including sweet, salty, bitter, and sour and encourages consumption of energy- and nutrient-rich foods while encouraging the avoidance of possibly toxic or harmful foods. Supertasters, who are more sensitive to taste and other oral sensations, live in a different taste world from that experienced by nontasters. In addition, taste sensitivity, at least for certain bitter stimuli, is more prominent for women and varies with the menstrual cycle with a peak during the first trimester of pregnancy. Meanwhile, taste contributes only a part of the typical experience of consuming food. Flavor, that aspect of food consumption that we all enjoy most, is made up of the sensation of taste, smell, and the somatosensory experience of the texture of the food. So, while taste plays an important role in allowing us to obtain nutrients and avoid possibly harmful substances, it is only one part of the food consumption experience.

Synonyms

[Body and hand gestures](#); [Chew-chew theory](#); [Oral gesture theory](#)

Definition

Ta-ta theory states that humans made the first words by tongue movements that mimicked the movement of the hands, face, or other parts of the body and translated them into audio.

Introduction

According to Richard Paget, the *ta-ta* hypothesis supported that speech and the development of

sound were produced to endorse the hand and body movements of the individual. So as to better demonstrate the meaning behind the gestures, these sounds developed different words or combinations of sounds unavoidably leading to speech patterns (Paget 1930). For instance, when a person would say *ta-ta*, he was basically saying goodbye with his tongue. At some point, this theory was even supported by Charles Darwin (Mandavilli 2016). In the literature, there are several theories such as the *oral gesture theory* and the *chew-chew theory* that support the idea that the origin of language begun from early human gestures made from their mouth. It is of paramount importance, though, to understand that it is not feasible to explain the origin of some words using the *ta-ta theory*.

A major drawback of this early theory on the origins of language is the fact that in order for people to be able to communicate between them, they must see each other in person. Also, there must be daylight, or firelight, and with nothing blocking one's view. In the case of hand gestures, it is important that hands are free from doing something else (Meir et al. 2010). Last but not least, in order for this hypothesis to be the origination of communication, it required a number of gestures be in place already for humans to imitate with their mouth gestures, but it didn't explain how these gestures arose in the first place.

Conclusion

Originally hypothesized by Richard Paget, and later supported by Charles Darwin, the *ta-ta theory* suggested that the origin of language commenced from the use of tongue and mouth gestures imitating the movements of the body and hands. As commonly seen in primates, gestures such as hand and body movement are important aspects of communication and collaboration within societies (Paget 1930). In spite of the fact that it is probable like many of the other hypothesis, the cultural roots of various hand gestures states that this is most likely not the cause behind verbal communication.

Department of Psychology, University of Nicosia, Nicosia, Cyprus

Synonyms

[Athletic competition](#); [Sports](#); [Team athletes](#)

Definition

Any sports activity where two or more players cooperate towards achieving a common objective while they compete against an opposing team. Some examples of team sports include, but are not limited to; soccer, baseball, basketball, American football, hockey, volleyball, and handball.

Introduction

Poliakoff (1987) defined sport as “an activity requiring direct physical competition with an opponent(s), has established procedures and rules, and defined criteria for determining victory” (as cited in Lombardo 2012). The direct goal of a sporting engagement is winning the activity regardless of any other extrinsic rewards that follow the victory, such as earning a trophy or a medal; hence, the core nature of the competition still remains unchanged (Lombardo 2012). Whether conceptualized as functional integrated “super-organisms” (Duarte et al. 2012), complex social networks (Ribeiro et al. 2017), or stripped-down to examine evolutionary benefits, such as gaining prestige (De Block and Dewitte 2009), team sport at its essence remains a fun and entertaining activity for everyone involved. At the moment in the USA, baseball, basketball, and American football are the most widespread team sports played (Budd and Egea 2017).

Groups Versus Teams

Weinberg and Gould (2011, p. 160) explain that merely going out with your friends to watch the “game” does not necessarily make you a group for the reason that group members are characterized by both having a mutual interaction and an interdependence for a shared objective as well. Furthermore, they discuss that some of the similarities between groups and teams include: a potential occurrence of mutual romantic attraction between members and all members share a common goal (e.g., all the members in a fitness class may strive towards weight loss and muscle definition). However, even though both groups and teams interact with each other and depend on each other for a common purpose, sports teams additionally exhibit the following four key components: “(a) Collective sense of identity – ‘we-ness’ rather than ‘I-ness’, (b) Distinctive roles – all members know their job, (c) Structured modes of communication – lines of communication, (d) Norms – social rules that guide members on what to do and not do.”

Team Dynamics

An effective way to increase performance, enhance team spirit, and manage conflict between the team members is to promote outcome interdependence (i.e., members realize that the teams successes and failures has an equal positive or negative effect, respectively, on all of them) by communicating constructive feedback to the whole team to reinforce shared responsibility for the team’s performance and outcome (Weinberg and Gould 2011, p. 170).

Weinberg and Gould (2011, pp. 174–177) emphasize the importance of recognizing and inhibiting the effects of social loafing (i.e., the psychological phenomenon where individual members in a group do not use their full effort to achieve a team goal because of motivation loss and responsibility diffusion) in order to maximize individual performance in a sports team. Furthermore, the authors suggest that because studies show that team success is only partially dependent on each

player’s individual skill level, the following practices are needed to boost each player’s individual contribution and eliminate social loafing in a team; coaches need to (1). Help players recognize their unique contributions to the team and assume responsibility and pride for the team’s welfare, (2). Videotaping team practices and games can make individual contributions known to all members showing that individual efforts are identifiable, (3). Videotaping or other observations additionally aid in the identification of possible social loafing occurrences and the situations under which the team is most often prone to social loafing, (4). Discuss social loafing individually with every member of the team and examine their motivation, (5). Cultivate the players’ understanding for their teammate’s unique role and challenges by rotating players to all positions at least for a short duration, and (6). The team can be divided into smaller subgroups where responsibility is more easily recognized and reinforced while still emphasizing on the overall team effort to avoid the formation of social cliques which results in the disruption of team cohesiveness.

Team sports are commonly characterized by the aggression exhibited from both the opposing team players and their fans. To examine aggression in team sports, Coulomb-Cabagno and Rasle (2006) videotaped and observed 180 soccer and handball games from different competitive levels. Their analysis revealed that aggressive behaviors were more common in male rather than female players with larger gender difference found in handball than in soccer, and at higher competitive levels, instrumental aggressive behaviors (i.e., hurting another player during the game to achieve a competitive goal) increase and hostile aggressive behaviors (i.e., hurting another player during the game for the sake of causing him or her harm) decrease.

The Evolution of Sport

Ranging from cave paintings and stone slabs to monuments, traces of athletic events in societies provide evidence that sports have existed in the past, for thousands of years. In 776 BC, the first ever Olympic Games were inaugurated in Greece,

colonization during the early nineteenth and twentieth centuries promoted team and individual sports across the world while the involvement of North America and Western Europe in this historical phenomenon largely structured the rules and format of modern-day sport, while after the innovation of global communication and mass media in the 1960s, sport begun to gain increased popularity as a profession (Budd and Egea 2017).

In ancient societies only men were allowed to participate in sports; however, in contemporary societies even though men still constitute the majority of athletes the advocacy for women's rights has successfully aided in increasing the number of women that participate in sporting competitions (Budd and Egea 2017). Men initially began participating in sports as a low-cost way to develop the necessary skills required for physical rivalry, primitive hunting, and warfare and later evolved as a means to practice and improve their physical abilities, provide grounds for displaying prowess to attract potential mates, hence increase their reproductive success, and finally, an opportunity to evaluate their potential allies and rivals in terms of their strengths and weaknesses so that they can adapt and appropriately interact with them in the future (Lombardo 2012).

One explanation suggests that sport has evolved through culture as a ritualistic way to present individual physical prowess and attract sexual partners (De Block and Dewitte 2009). From a Darwinian perspective, sports evolution is predicated on three aspects that help determine the fittest contestant: "informativeness," "accuracy," and "transparency." A viable sport is "informative" when it adequately assesses the evolutionary qualities (i.e., the ones related to survival and reproduction) of the competitors, such as their strength, dexterity, intellect, agility, etc., "accurate" meaning that the winner possessed maximum level of skill and minimum level of luck which is largely determined by a fair set of rules, and "transparent" when the audience is able to clearly understand and recognize that the winner was more powerful than the other contestants (De Block and Dewitte 2009).

Team sports, not only improve individuals' status in their communities and sexual attraction from the opposite sex but are also tests invented by the human culture to assess other peoples' ability to work together as a team (e.g., teamwork and cooperation skills) and to utilize their leadership and followership skills (De Block and Dewitte 2009). In addition, men mainly because of an overall higher natural physical fitness tend to perform better in sports than women (Lombardo 2012). Lastly, since men and women rather than primarily focusing on the opposite gender's team sports they exhibit great interest in observing their own gender's team sports, it suggests that team sports have not purely evolved to serve mate choice but at least to a certain degree assist in the improvement of one's physical abilities (De Block and Dewitte 2009).

Involvement in Team Sports Matters

Evidence on the positive benefits of team sports involvement illustrate that the social interaction with peers facilitated through team sports promotes social acceptance in a less threatening environment among marginalized adolescents, and the risk for depressive symptoms associated with dissatisfaction about one's own body image is diminished through the social support, improved physical fitness, and the opportunity to appreciate one's current body's physical appearance and capabilities, offered by the participation in team sports (Boone and Leadbeater 2006). Additionally, students who participate in school team sports tend to exercise more and show higher rates of "milk consumption, and healthy self-image, and significantly lower odds for emotional distress, suicidal behaviour, family substance abuse, and physical and sexual abuse victimization" (Harrison and Narayan 2003). An unexpected finding in Harrison and Narayan's (2003) study was that adolescents who were victims of abuse or experienced substance abuse in their families reported less involvement in sports (a partial explanation for this was contemplated

around a tendency for social isolation exhibited from victims of abuse).

A systematic review of 30 published studies reported that the most common psychosocial health benefits related with participation in sports are higher self-esteem, improved social interaction, and fewer depressive symptoms, while team sport participation when compared to individual activities has the added benefits of being associated with better health outcomes, because the social nature of team sports provides social support and promotes social acceptance (Eime et al. 2013). Last but not least, even though women are less likely to participate in team sports than men, they too reap the same benefits from the positive environment cultivated in sports teams once they do join a team (Boone and Leadbeater 2006).

Conclusion

Undeniably sport places a major impact on the economy, is considered by many people their favorite recreational activity, and is widely embraced by the public as a sensible practice for a healthy lifestyle (Budd and Egea 2017). What is more, for adolescents, a positive involvement in team sports offers unique benefits over and above the engagement in any other extracurricular activities (Harrison and Narayan 2003). Admittedly, when all is said and done, the most important fact may very well be that irrespective of gender, age, ethnicity or ability, team sports are a fun and enjoyable activity for everyone, especially during the twenty-first century where there are hundreds of available sports to choose from (Budd and Egea 2017).

Definition

The need to efficiently organize behaviors requiring a high number of sequential operations leads to selection for increased intelligence.

Introduction

The technical intelligence hypothesis is one of the most popular explanations for the evolution of human intelligence. It posits that the need to efficiently organize behaviors requiring a high number of operations led to the evolution of increased intelligence (Whiten and Byrne 1997). The hypothesis was first proposed by Byrne and Whiten as an alternative to the social intelligence hypothesis (cf. Byrne and Whiten 1989; Whiten and Byrne 1997), as within primates, great apes appeared to show certain cognitive skills that could not be explained by differences in social organization.

How to Test for the Technical Intelligence Hypothesis?

Testing the validity of the technical intelligence hypothesis is challenging. It first requires to define what we mean by intelligence. Second, it requires an operational measure of a species' ability to

efficiently organize behaviors requiring a high number of sequential operations. Tool use and manufacture and rates of technical innovations in the wild are the measures that have been considered in the literature. Third, it requires characterizing the cognitive skills of species, ideally by considering skills expected to favor tool use and technical innovations (for example, physical cognition skills such as object manipulation, fine motor control and problem-solving), that should have been directly targeted by selection if the technical intelligence hypothesis is true. As the brain is the organ involved in cognition, testing whether species displaying the ability to develop these complex behaviors also have disproportionately larger brains should also inform us on the cognitive demands of technical innovation. Finally, the causality of an eventual association between tool use/technical innovation and (physical) cognitive skills needs to be assessed, which likely is the most challenging step.

Tool Manufacture and the Technical Intelligence Hypothesis

Early attempts to define the unique intelligence of humans were based on the ability to manufacture and use tools (Oakley 1956), with the underlying idea that human intelligence evolved, at least partly, in response to the need to manufacture tools. However, as hominins were and still are both tool manufacturers and highly social, it is very difficult to distinguish between the social and technical intelligence hypotheses considering our clade alone. The discovery that many animals beside humans also manufacture and use tools in the wild allowed researchers to investigate the general importance of tool use in the evolution of intelligence.

Tools are objects that are used as an extension of the body and held directly in the hand or mouth (see Shumaker et al. 2011 for a more complete definition). As to manufacture and use tools, an animal needs to carry out a number of successive steps in an organized order, tool manufacture and use is a good candidate behavior to investigate the technical intelligence hypothesis. Several dozens

of species, from invertebrates to birds and mammals, have been reported manufacturing and using tools in the wild (Shumaker et al. 2011), making it possible to compare encephalization and cognitive skills of tool-using species with closely related non-tool-using ones. In birds, there is a correlation between tool use and both relative brain size (Lefebvre et al. 2002) and brain structures involved in motor control and learning (Iwaniuk et al. 2009). The New Caledonian crow *Corvus moneduloides*, which shows the most sophisticated forms of tool use and manufacture of all birds (Taylor et al. 2007), also displays a larger brain, relative to its body size (Cnotka et al. 2008), and a larger mesopallium (a brain region equivalent to the nonvisual cortex), relative to brain size (Mehlhorn et al. 2010), than other corvids not known to use tools in the wild. In primates, tool use frequency correlates with both absolute and relative brain size, larger brained species using tools more frequently (Reader and Laland 2002). Overall, tool-using species thus seem to display larger brains, suggesting that tool use requires higher intelligence. The next step was thus to test for association between cognitive skills and tool use.

Using tools is expected to require a certain understanding of the physical environment. Physical cognition, rather than other cognitive skills such as general learning, is thus expected to be a tool-related specialization. Under the technical intelligence hypothesis, tool-using species should perform better on physical cognition tasks than non-tool-using species. Comparing performance on physical cognition tasks in tool-using and non-tool-using sister species however yielded contrasting results. In birds, the tool-using New Caledonian crow outperformed the non-tool-using carrion crow in a physical problem (the cane task, whereby an individual has to choose between pulling two hook-shaped tools laid flat on a surface, the spatial relation between the food and the hook being different (inside or outside of the hook); Teschke et al. 2013). However, in the same study, no difference was detected between the tool-using Galapagos woodpecker finch and its non-tool-using sister species, the small tree finch (Teschke et al. 2013). A range of physical

cognition tasks were also tested on both tool-using and non-tool-using primates (especially apes). In a recent review, Taylor and Gray (2014) showed that although some differences exist, they are largely inconsistent. In addition, most if not all such comparative analyses suffer from potential biases in sampling effort: the sample size is too low, at least for one of the species considered, to conclude with regard to the overall species' performance. Finally, biases associated with differences in developmental history also limit the interpretation of these studies. In many studies, individuals from tool-using species born in the wild were compared with individuals from non-tool-using species born in captivity. These differences are likely to condition individuals' response to the tests and may thus strongly bias the results. Aside from the larger brain of tool-using primates and birds, as compared to their non-tool-using sister species, evidence for increased cognitive skills associated with tool use and manufacture is thus scarce and debatable.

Technical Innovations and the Technical Intelligence Hypothesis

Considering tool use behaviors to investigate the technical intelligence hypothesis has some limitations, especially because of the rarity of this kind of behavior in the wild. Comparative analyses on tool use thus traditionally focus on a limited number of species from specific taxonomic groups (e.g., Corvids or Apes). In addition, considering exclusively tool use and manufacture to investigate the technical intelligence hypothesis is likely reductive (Huber and Gajdon 2006), as other behaviors are likely to also require organized, sequential operations. An alternative approach, initiated by Overington et al. (2009), has been to collect data on the incidence of "technical" innovations in wild animals, with the assumption that a higher number of technical innovations in a particular clade reflects a better ability to express behaviors requiring a high number of sequential operations.

An innovation is a solution to a novel problem or a novel solution to an old one (Kummer and

Goodall 1985). To develop an operational measure of a species' innovativeness (or propensity to produce innovations), Lefebvre et al. (1997) scanned ornithological journals for reports of birds' departure from the standard behavioral repertoire of a species. The number of foraging innovations published in these journals for each species was then used as a measure of a species' innovativeness (after correction by potential confounding factors, such as research effort). This database has since been extended to several regions of the world for birds (Lefebvre et al. 2016) and a similar database has also been developed for primates (Reader and Laland 2002).

Using these databases, Overington et al. (2009) and Navarrete et al. (2016) extracted the innovations that could be considered as "technical," to develop an operational measure of technical innovativeness. These studies, and especially the definition of technical innovation they considered, did not directly aim at testing the technical intelligence hypothesis. However, the metrics and methods they developed can inform us on the relevance of this hypothesis. Overington et al. (2009), working on birds, defined technical innovations as reports where the author described the foraging technique itself as novel, regardless of whether the food type was novel or not. In this framework, innovations involving novel techniques, novel parasitic behavior, novel commensal behavior, novel mutualistic behavior, novel prototool behavior, novel true tool behavior, or novel caching behavior were considered as technical innovations. In primates, Navarrete et al. (2016) considered as technical innovations either tool use or innovative extractive foraging behaviors. These innovations do not necessarily imply behaviors requiring a high number of sequential operations and may thus not allow a direct test of the technical intelligence hypothesis. However, they fit with a broader definition of this hypothesis and as such can inform us on how plausible it might be.

In both birds and primates, species with a higher number of technical innovations also have larger brains, relative to their body size (Overington et al. 2009; Navarrete et al. 2016),

in line with the larger brain of tool-using species as compared to non-tool-using ones. In addition, the correlation between rates of technical innovations and brain size is stronger than between brain size and the number of opportunistic innovations (such as the incorporation of new food types in a species diet), also supporting the idea that these technical innovations require higher cognitive abilities. Although these results suggest that the ability to produce complex new behaviors requires a particular combination of cognitive abilities, whether the need to develop such behaviors actually drove the evolution of larger brains, and of a higher technical intelligence, is debatable.

Did Tool Use/Technical Innovations Drive Brain Enlargement and the Evolution of Intelligence?

The technical intelligence hypothesis is an evolutionary theory. It suggests that the use of tools and the need to develop technical innovations led to an increase in encephalization and intelligence. The hypothesis can thus be considered a refinement of the extractive foraging hypothesis (Parker and Gibson 1977), which argues that the need to obtain some embedded or hard-to-eat food might have favored the evolution of large brains.

Under the technical intelligence hypothesis, the innovative ability to organize behaviors requiring a high number of sequential operations is a specialized adaptation. However, there is little evidence that technical problem-solving is a specialized cognitive function. Indeed, the finding that some birds (e.g., rooks *Corvus frugilegus*, Bird and Emery 2009) and primates (e.g., gorillas *Gorilla gorilla*, Mulcahy et al. 2005) that do not use tools in the wild perform well on tool use problems in the laboratory suggests that the special cognitive abilities of tool-using species have preceded the evolution of tool use (Kacelnik 2009).

Alternatively, the ability to innovate in a technical context may not be the direct target of selection, at least in the early stages of evolution. Instead, this ability may appear as an emergent property associated with the evolution of traits

that have evolved for other functions and that, combined, predispose animals to solve problems through technical innovations (Sol 2015; Sol et al. 2016). The evolution of large brains (which may have evolved for other reasons unconnected with technical intelligence) might have facilitated the emergence of the cognitive abilities required for tool use and technical innovations (Sol 2015; Navarrete et al. 2016).

This is particularly likely in long lived, generalist species searching for ecological opportunities, such as chimpanzees and corvids, all known to have the ability to use tools (Ducatez et al. 2014; Sol et al. 2016).

Conclusion

The technical intelligence hypothesis is difficult to test. Defining and measuring technical intelligence is challenging. Yet demonstrating that the need to efficiently organize behaviors requiring a high number of sequential operations has been a major evolutionary pathway toward enhanced intelligence is even more challenging. Current evidence suggests that these complex, technical behaviors emerged in species with relatively large brains. Whether these larger brains are the cause or the consequence of the need for higher technical cognitive abilities remains debatable. More investigations, especially on the differences in physical cognition between phylogenetically related tool-using and non-tool-using species, are needed to better understand the plausibility of the technical intelligence hypothesis.

[Telomere](#); [Telomeric repeat sequence](#)

Definition

The enzyme that acts to maintain the end of DNA molecules in the chromosomes of eukaryotes.

Introduction

Telomeres are the strands of DNA at the ends of eukaryotic chromosomes. They consist of sequences that repeat, although the specific sequence varies by species of eukaryote. They perform several important functions. One of the

most crucial is the protection of chromosomes from exonuclease enzymes, which are capable of degrading the terminal regions of chromosomes. Additionally, they ensure that the natural repair systems of DNA do not detect the ends of chromosomes and join them together. Therefore, telomeres ensure that chromosomes remain intact and that DNA replicates efficiently and effectively (Moyzis et al. 1988).

Because of the way that DNA replicates, telomeres should get progressively shorter with each successive round of replication. This is because DNA can only be copied in one direction, which causes the other strand to lag behind. Therefore, the second strand can only be copied in fragments, called Okazaki fragments (Pohjanpelto and Hölttä 1996). Often the last Okazaki fragment is not primed, which leads to a difference in length between the two strands of DNA. Additionally, the final Okazaki fragment can be positioned too close to the end of the DNA molecule. Both of these would result in the gradual shortening of DNA molecules, but telomerase counteracts this process by adding to the ends of DNA strands (Harley et al. 1990).

Telomerase is a unique enzyme because its constituents are both protein and RNA. Contained within its RNA sequence is the reverse of the telomeric repeat sequence. Because of this, telomerase is capable of binding to the telomeric repeat sequence and lengthening the lagging strand of DNA. It is through this mechanism that telomeres are maintained throughout the many cell divisions that must occur in order for organisms to survive (Chen et al. 2000).

Empirical Support

Extensive evidence has supported the existence of telomerase. After telomeres were identified, investigations of the mechanism by which they are extended were undertaken. The first investigation of telomerase were carried out by Blackburn and others using yeast as a model organism. This investigation showed a progressive shortening of telomeres across successive generations of yeast cells. It also supported the role of telomerase in counteracting this process (Blackburn et al. 1989).

Building on this work, other researchers have found evidence of telomerase activity in other organisms, most notably humans (Henderson et al. 1990). In humans, telomerase has been implicated in both normal processes such as aging, as well as abnormal processes, such as cancer.

The shortening of telomeres has been shown to be implicated in the normal aging process. In other words, as humans age, their telomeres get shorter. Therefore, the presence of telomerase is important for extending the life span of humans. Many studies have confirmed the link between the length of telomeres and aging (Greider 1990). Telomere length and the functioning of telomerase have also been shown to be related to disorders common in the aging population, such as dementia, as well as disorders that are marked by abnormal aging processes. Related to this, the functioning of telomerase has been shown to be related to these disorders. These disorders have been shown to occur when the telomerase enzyme is defective or when other enzymes related to the process do not function properly. For example, people with progeria, a disorder marked by premature aging, have been shown to have shorter telomeres than other people. This suggests a failure of telomerase to extend telomeres, which contributes to the characteristic features of progeria (Ding and Shen 2008).

Telomerase can also become overactive. This defect has been implicated in the formation of cancer, which is characterized by cells that rapidly divide and do not die. An abundance of telomerase has been seen in cancer cells. The function that telomerase performs in normal cells, which is to help them to divide, helps to support the rapid division of cancer cells. In cancer, telomerase is often over active. As a result of this, telomeres become longer than they normally are, which leads to more divisions of that cell. This excessive cell division gives rise to tumors and other hallmarks of cancer (Shay et al. 2001).

Importance to Evolutionary Psychology

Telomerase can be found in all eukaryotic cells, including animals and plants. This means that it has been conserved throughout the evolution of

eukaryotic organisms. This maintenance over millions of years of evolution points to its importance in maintaining the integrity of DNA. Its importance is likely due to its ability to stave off aging, as evidenced by its expression in diseases of aging. Evolution is predicated on survival and reproduction, so telomerase has direct implications for evolution by supporting these crucial processes.

Evolution occurs as a result of genes mutating as they are passed from one generation to the next. Telomerase ensures that DNA will successfully replicate, which allows organisms to survive and reproduce, which allows genes to pass to the next generation. Therefore, by allowing chromosomes to maintain their structure, telomerase plays an important role in the continued evolution of the human species. Because most, if not all, psychological traits have been shown to have genetic components, they are acted upon by evolution. Therefore, telomerase allows for the evolution of psychological traits by protecting the parts of DNA that contain genes.

Conclusion

Telomerase plays an important role in the maintenance of the telomeres on the ends of chromosomes. Telomeres are important for protecting genes and allowing genetic material to be transmitted from one generation to another. Telomerase lengthens telomeres after DNA replication, which counteracts the shortening of telomeres that occurs during the replication process. Because of this, it plays an important role in the maintenance of life and the passage of genetic information from one generation to the next.

Definition

Telomeres, the protective caps of chromosomes, shorten with cellular division and age. Shortening may be hastened by exposure to environmental factors including psychosocial stress.

Introduction

Telomeres are nucleoprotein structures that buffer and stabilize the ends of all linear eukaryotic chromosomes. They are evolutionary ancient structures that emerged in response to the chromosomal end replication problem. Telomeres shorten with age, and cells with critically short telomeres either die off or cease to replicate. Accordingly, short telomeres are a risk factor for increased morbidity and mortality in humans and are thus likely to have fitness consequences. In addition to age-dependent telomere depletion, there is evidence that environmental factors, including experiences of psychosocial stress, may hasten telomere shortening.

Overview

Telomeres consist of DNA repeats that function to buffer the coding portions of our genomes, as cell division results in the loss of roughly 50–200 base pairs (bp) due to incomplete end replication (Wright et al. 1997). This loss occurs because DNA replication machinery cannot bind to the ends of linear chromosomes, a phenomenon known as the “end replication problem” (Lingner et al. 1995). Once telomeres reach a critical minimal length, cells either cease to divide or die. Accordingly, the inability for tissues to replace cells impairs health and fitness, and short TL is linked with increased disease and mortality risk in humans and other vertebrates (Cawthon et al. 2003; Wilbourn et al. 2018).

While TL shortens with age, the rate of decline is not the same in all individuals. Numerous environmental factors ranging from smoking to psychosocial stress correlate with shorter TL (Astuti et al. 2017; Willis et al. 2018).

Furthermore, associations between environmental factors and TL are observed throughout the human lifespan, with early exposures generally having a larger association with TL than those experienced during adulthood (Mathur et al. 2016; Ridout et al. 2017; Shalev et al. 2012). Even environmental exposures experienced during intrauterine life correlate with postnatal TL, measured both at birth and during young adulthood (Entringer et al. 2011, 2013).

Experimental investigations using both *in vitro* cell lines and animal models have established mechanistic pathways that may connect these environmental factors with accelerated telomere depletion. These pathways include increased inflammation levels, oxidative stress exposure, and chronic stress hormone exposure (Choi et al. 2008; Haussmann et al. 2012; Kawanishi and Oikawa 2004; Nettle et al. 2017). The contribution of each of these pathways to human telomere depletion, however, remains unknown, as our understanding of the effects of environmental factors on TL in humans almost exclusively comes from correlational studies. While most of these studies assume a causal relationship between environmental factors and shorter TL, alternative pathways exist to explain these findings.

What Are Telomeres?

Telomeres are the ends of linear eukaryotic chromosomes. They are nucleoprotein structures that consist of repeated, noncoding DNA bound to the structural protein shelterin. Due to the end replication problem, telomeric DNA shortens with cell division. When cells have critically short telomeric DNA, they are signaled to cease replication. This signal is thought to be mediated through the uncapping of shelterin from short telomeres (Cookson and Laughton 2009; Lendvay et al. 1996).

Cells that undergo rapid division maintain their telomeres with an enzyme called telomerase. Telomerase functions to rebuild short telomeres by adding repeated telomeric DNA to the 3'-end of the chromosome. Next, after telomerase adds enough substrate, DNA polymerase binds and adds the complementary DNA repeats to the telomere (Blackburn 1992). In most human tissues, telomerase is only active during embryonic

development. However, in tissues that continue to proliferate into adulthood, like blood (i.e., leukocyte progenitors), telomerase remains active, albeit at levels that cannot sufficiently maintain TL (Iwama et al. 1998). Both TL and telomerase activity are vital to cellular maintenance, are presumed to have a causal role in health and fitness, and may explain variation in important life history traits.

Telomere Evolution

Telomeres have a deep evolutionary past, as variations of the repeated telomere DNA sequence are present in every major eukaryotic lineage. Ancestral chromosomes like those in prokaryotes and mitochondria are circular; thus, neither have telomeres nor are subject to replicative DNA loss. With the emergence of linear chromosomes, telomeres evolved as a buffer of noncoding DNA to minimize the risk of the end replication problem (Volff and Altenbuchner 2000). Telomerase may have an even deeper origin, possibly dating back to the RNA world (Eickbush 1997).

TL differs widely across taxa, which makes sense considering that eukaryotes face radically different selective pressures and have lifespans that can vary by over five orders of magnitude (Blackburn et al. 2015). Among 61 studied mammalian species, those with longer lifespans tend to have shorter telomeres (Gomes et al. 2011). The shorter telomeres of long-lived mammals generally are subject to cellular aging, while those in shorter-lived mammals are less affected by cellular aging. A theory used to explain this difference is that TL is under relaxed selection in short-lived animals, with other aspects of their life histories subsequently accelerating their aging (e.g., increased metabolic rate and high reproductive burden).

TL also varies within taxa. For example, in humans, females tend to have longer telomeres than males, which is concordant with females' generally longer lifespans (Kimura et al. 2008). In humans, TL is substantially heritable ($h^2 \approx 0.70$) (Broer et al. 2013). Telomere depletion rates may also be heritable, although it is difficult to tease apart the genetic and environmental effects on TL (Monaghan 2010).

Environmental Exposures Correlate with Depleted Telomere Length

In humans, numerous environmental factors correlate with shorter telomeres, including psychosocial stress, smoking, exposure to heavy metals, radiation, and poorer nutrition (Astuti et al. 2017; Lustig et al. 2016; Rafie et al. 2016; Zota et al. 2015). Of these, socioeconomic status (SES) and perceived stress are the most commonly explored (e.g., Tennyson et al. 2018), with many studies reporting weak to moderate correlations indicating shorter TL in low SES, high stressed individuals (Willis et al. 2018). While support for the association between different stress measures and TL varies across studies, one consistently observed trend is that early life stress better predicts TL than adult stress (Mathur et al. 2016; Pepper et al. 2018; Ridout et al. 2017; Willis et al. 2018). This finding may be explained by individuals being more vulnerable to environmental damage early in life because the rate of developmental change and cell turnover in their bodies is at its fastest (Eisenberg 2011; Gavrilov and Gavrilova 2004). Intriguingly, the effect of early life adversity on TL may stretch back to even before birth, as emerging evidence indicates that the intrauterine environment associates with human TL at birth, as well as the rate of telomere depletion during early life and subsequently TL during young adulthood (Entringer et al. 2011, 2013; Escoffier et al. 2018).

Causal Models and Alternative Hypotheses Explaining Correlations

While ample studies show correlations between environmental factors and TL, we still do not know the extent to which they shorten telomeres. One way to better ascertain the mechanisms of telomere depletion is to explore the multiple pathways that may mediate these associations. Some of these proposed pathways include increased inflammation, oxidative damage/stress, and chronic glucocorticoid exposure. Chronic inflammation increases the rate of cell turnover, which subsequently shortens TL (Nettle et al. 2017). Oxidative stress can directly cleave the vulnerable GGG regions of the repeated human telomere DNA sequence (Oikawa and Kawanishi

1999). Chronic exposure to stress hormones is known to both inhibit telomerase and shorten TL (Choi et al. 2008; Haussmann et al. 2012). Since it is unethical to test these pathways experimentally in humans, most of these data exist from either *in vitro* cell line or *in vivo* vertebrate studies. As such, skepticism remains regarding the actual effect of each pathway on human TL.

Bateson and Nettle (2018) recently suggested that much of the telomere literature too readily assumes that the correlations with environmental exposures reflect a simple causal relationship. Life history theory suggests that those faced with an uncertain future may adaptively exhibit more risky behaviors and devalue their future health (Wilson and Daly 1997). Shorter TL predicts poorer health outcomes (Cawthon et al. 2003). Thus, it may be that individuals with shorter telomeres are more likely to engage in behaviors that are detrimental to their health because of facultative adjustments to their life history strategies. Indeed, shorter TL predicts increased impulsivity and risk taking in young and healthy undergraduates (Yim et al. 2016).

Another causal scenario to consider is that a third variable, possibly early life stress, affects both behavior and TL (Bateson and Nettle 2018). Increased exposure to stress early in life predicts both shorter telomeres and an increased likelihood of adopting certain risky behaviors (e.g., smoking and poor diet) (Boonekamp et al. 2013; Lovallo 2011; Manuck and McCaffery 2014; Shalev et al. 2012). As such, there may be TL-independent pathways that mediate the linkage between stress and behavior, a scenario that subsequently relegates TL as a noncausal biomarker.

The Future of the Field and the Need for Longitudinal Research

It has long been assumed that environmental and behavioral factors shorten telomeres. While experimental data shapes our understanding of the pathways that link environment, TL, and biological health, mostly weak to moderate correlative evidence exists from human studies. These results, along with evidence suggesting a noncausal relationship between certain environmental factors and TL (e.g., smoking by Rode

et al. 2014), have led some to question the long-held assumption of causality (Bateson and Nettle 2018). While it is difficult to ethically measure environmentally mediated telomere depletion in humans under experimental conditions, longitudinal research may provide a promising alternative.

By measuring telomere depletion rather than TL, longitudinal studies allow researchers to account for the variable starting telomere lengths observed among human individuals. Thus, they provide the capacity to better resolve issues of causality. To date, however, only limited longitudinal research has been conducted. These studies average between 4 and 5 years between baseline and follow-up and have frequently used potentially biased statistical methodologies (Bateson et al. 2018). Humans are a long-lived species; a lengthier assessment of telomere depletion with better statistical methods will likely offer more resolution and better causal inference. By studying how telomeres change over time, researchers can determine if risky adult behaviors cause telomeres to shorten or if another factor like early life stress both shortens TL and causes risky behaviors. Discovery of the latter would indicate that the correlations used to infer causal pathways between behavior and TL may, in reality, be indirect. By using a longitudinal design, researchers can also test if individuals with shorter telomeres are more likely to engage in risky behaviors. Finally, by better comprehending the factors that shorten telomeres, we can also assess the possible factors that attenuate or even reverse telomere loss. The idea that lifestyle, social solidarity, resilience, and other factors such as religiosity can attenuate telomere depletion is of considerable interest, especially as the causal role of TL in health and fitness is better understood (Hill et al. 2016; Ornish et al. 2013).

Conclusion

Telomeres are ancient structures that emerged early on in the evolution of eukaryotes. As linear chromosomes shorten with cell division and age, telomeres buffer the genome from nucleotide loss and convey protection against the premature

cessation of cellular replication and cell death. In addition to age, environmental factors, including experiences of psychosocial stress, may shorten TL. Short TL subsequently predicts an array of disease phenotypes as well as increased mortality risk. While mostly correlative data exists for humans, novel experimental data collected from both *in vitro* and animal model studies now allow for the proposal and exploration of causal mechanistic pathways. Hypotheses generated by these data will soon be tested in humans as longitudinal studies may finally have enough time between baseline and follow-up to capture meaningful results in such a long-lived species. The results from these studies will allow better inference of causation, as well as improvements of the understanding of how behaviors and lifestyle choices attenuate the effect of stress on TL.

Definition

Under stress, the need to affiliate with others is an adaptation that enhances survival.

Introduction

Taylor et al. (2000) posited a “biobehavioral” (behaviors that have biological underpinnings) hypothesis regarding the survival instincts of human beings, arguing that the fight-or-flight response is a mislabeling of responses to stressors in human females. The tend-and-befriend hypothesis states that under times of stress, females are more likely to utilize behaviors different from fighting or fleeing, i.e., parenting (tending) and affiliative behaviors (befriending) that protect both themselves and their offspring from stress, whereas males exhibit the classic fight-or-flight sympathetic nervous system response to stress.

The theory offers evidence that the biological underpinnings are (1) the hormone oxytocin and (2) the opioid system, which are central actors that facilitate the tending and befriending behaviors of females under stress. Since its publication in 2000, its influence in the conceptualization of sex differences in physiological stress responses and observational research of psychological stress has fundamentally shifted and enhanced the scientific study of the interplay between observed behaviors and the biological underpinnings of those behaviors.

Tend and Befriend Theory

The crux of tend-and-befriend adaptations lies in the argument that the theory of the fight-or-flight responses shown in animals (Cannon 1932) was largely based on male-biased samples in both human and nonhuman animal research. Fighting or fleeing may be advantageous to males when threatened, whereas they may not offer the same advantages to females, particularly for females with offspring under their care. Fighting or fleeing may put the mother and her offspring at risk in a species that show typically higher maternal investment in offspring (meaning time and effort offered in parenting behaviors). Therefore, in response to stress, females will tend to offspring, and as a piggyback onto that biobehavioral system, will befriend other conspecifics (especially other females) for protection/buffering from stress (Taylor et al. 2000). Subsequent conceptualizations have refined the assumptions of tending and befriending adaptations (see Taylor 2012). Human studies, however, are observational in nature. Thus, nonhuman animal research has offered the bulk of support for the theory's claims regarding tending and befriending behaviors (Taylor et al. 2000).

Biological Underpinnings

Oxytocin and brain opioid systems are hypothesized to provide the biological bases of tending and befriending behaviors (Taylor et al. 2000). Oxytocin has been implicated in a wide array of

reproductive and parenting behaviors, stress, and social behaviors (see Carter 2014 for a current, comprehensive review). Evidence indicates that reactivity to stress releases may in fact create both a cascade of biological reactivity markedly different between the sexes and differential adaptive behaviors (tending and befriending vs. fight or flight) to facilitate the reduction of stress and subsequent calming of the biological responses to stress.

Evolutionary Advantages of Tending and Befriending for Females

Taylor et al. (2000) offer the hypothesis that the tending response (and related release of oxytocin) encourages maternal behaviors that facilitate the survival of offspring. As such, the evidence for tending behaviors in mothers are built on the attachment system between mothers and infants (Bowlby 1988). In addition, seeking support under stress (i.e., befriending) would attenuate stress in species whose survival depends on other conspecifics in cooperative groups. Thus, Taylor (2006) argues that “there would be clear survival benefits of a biobehavioral mechanism that signals gaps in social support and prompts affiliation for beneficial communal responses to stress” (p. 275).

Evidence for Tend-and-Befriend Adaptations

In recent years, evidence for (1) patterns in oxytocin and associated stress responses among human females, and (2) sex differences in stress reactivity have been studied in relation to tend-and-befriend adaptations.

Oxytocin and Stress Responses in Human Females
Evidence in human females is mixed regarding the effects of oxytocin on the behaviors of adults at different stages of life. For example, Heinrichs et al. (2001) found a stress response to the Trier Social Stress Test (TSST) regardless of whether lactating mothers held or breastfed their infants; however, cortisol responses were attenuated in breastfeeding mothers whereas oxytocin levels did not vary significantly in response to the stressor. In contrast, older women on hormone therapy showed higher oxytocin levels, and higher baseline oxytocin levels were associated

with greater self-reported relationship stress, but was not significantly related to stress reactivity to the TSST (Taylor et al. 2006). Subsequent conceptualizations (Taylor 2012) highlight differences in baseline oxytocin levels (but not reactivity) as predictive of perceptions and seeking of social support in adult females.

Sex Differences in Stress Reactivity

Although stress responses in the Hypothalamic–Pituitary–Adrenal (HPA) axis may be somewhat similar (via release of the hormone cortisol) in males and females in certain types tasks, the accompanying perceived stress of events may also offer insights into the observed differences in behaviors typically exhibited by males and females in response to those stressful events. For example, both male and female rowers showed significant cortisol responses to a *physical* task (rowing ergometer test); however, pretask cortisol levels in anticipation of the stressor were positively related to team bonding (i.e., befriending behaviors) in females, but social withdrawal (i.e., fleeing) in males (Kivlighan et al. 2005). Female rugby players showed differential patterns of cortisol and testosterone responses after a competition than previous studies of male competitors in team sports, indicating that there may be unique physiological cascades for females after a group-oriented challenge that is simultaneously psychologically and physically stressful to the individuals (Bateup et al. 2002). Additionally, in nonphysical tasks, males and females showed differential patterns of affiliative behaviors in the Ultimatum Game and the Prisoner’s Dilemma (Nickels et al. 2017), and Byrd-Craven and colleagues (Byrd-Craven et al. 2015, 2016) found sex differences in cortisol reactivity to a crying baby or an out-group threat.

Conclusion

Evidence in both human and nonhuman research offers support for tending and befriending behaviors as adaptive for human females, in particular, those who are distressed. The theory does not offer specifics as to the types of stressors that will cause the cascade of events that will

specifically elicit tending and befriending behaviors in females. However, subsequent research indicates that there are complex social and behavioral mechanisms that may trigger differential cascades of biological and behavioral reactions to stress for males and females in group versus individual threats and subsequent responses to those threats.

Since its publication, researchers have offered expanded definitions of tending and befriending behaviors in males (Geary and Flinn 2002), with mixed findings as to the physiological response cascades associated with social stressors between and among human females and males. For example, Berger et al. (2016) found differences among men participating in the TSST for Groups (TSST-G), suggesting fight-or-flight responses may not accurately characterize responses to stress in males. In addition, other researchers (e.g., Carter 2014; Del Giudice et al. 2011) have integrated tend-and-befriend into theoretical frameworks of biological and behavioral responses to a variety of stressors. Its hypotheses regarding behaviors and underlying biological mechanisms in humans offer myriad opportunities to test physiological and subjective measures of stress in both males and females, further informing the understanding of how a variety of stressors may affect humans.

Teratogenic Effects of Alcohol Exposure on the Fetus

Keshav K. Gupta
Birmingham, UK

Synonyms

[Adverse effects of alcohol in utero](#); [Fetal alcohol syndrome](#); [Fetal malformation](#)

Definition

The harmful effects of alcohol exposure on the developing fetus leading to its malformation.

Introduction

Alcohol is a well-established teratogen. If consumed by the pregnant mother, this can lead to a wide variety of physical and behavioral effects on the fetus. The range of these presentations can be grouped under the term fetal alcohol spectrum disorder (FASD). Within this spectrum, the most severe condition is called fetal alcohol syndrome

(FAS). This term was first formally coined by Jones et al. in 1973 who noted a group of characteristics seen in children born to alcoholic mothers. The incidence of FAS is difficult to measure on a global scale, largely due to the variability in its presentation. It is approximately seen in 0.5–3/1000 live births in the USA and Canada.

Alcohol as a Teratogen

The teratogenic effects of alcohol on the fetus that contribute to a diagnosis of FAS can be sorted into three main groups: growth deficiency, central nervous system (CNS) damage, and craniofacial abnormalities.

Growth

The growth deficiency in FAS can be assessed at any point during life and is defined as pre-/postnatal height or weight below the 10th percentile. This is used to contribute to FAS and partial FAS diagnoses but is not required to diagnose other diseases in FASD, including alcohol-related neurodevelopmental disorder (ARND). It is therefore postulated that growth retardation is a less important teratogenic effect of alcohol exposure during pregnancy (Institute of Medicine 1995). The rapid placental vasoconstrictive effects of ethanol is thought to contribute to the effects of growth deficiency through impaired delivery of oxygen and nutrients to the fetus (Burd et al. 2003).

CNS Damage

CNS damage is the primary feature for FAS diagnosis and can include a range of effects, including structural damage including microcephaly, cerebellar hypoplasia, and corpus callosum agenesis. This can be related to the teratogenic effects of ethanol on the developing fetal brain. The presence of ethanol at high levels lends itself to metabolism through a placental enzyme CYP2E1. This causes oxidation and generation of superoxide radicals which target and damage fetal brain tissue during their development (Gemma et al. 2007). Ethanol has also been shown to disrupt key neuronal developmental molecules such as alpha and

beta-laminins 1 which can contribute to microcephaly and intellectual disability (Minana et al. 2000; Vangipuram et al. 2008). More recent evidence suggests that ethanol can also interfere with trophoblast growth and cellular differentiation, which are both important steps in fetal development. This is seen with reduced levels of interleukins 6 and 13, signalling molecules specifically involved in neuroepithelial cell renewal and therefore contributing to adverse CNS development (Roberson et al. 2012).

Craniofacial Abnormalities

The presence of craniofacial abnormalities in FASD is usually as a consequence of brain damage. This is most likely linked to ethanol inducing uncontrolled cell death in cranial neural crest cells (Cartwright and Smith 1995). The three facial features associated with FAS are:

1. Smooth philtrum – the philtrum is the groove between the upper lip and the nose which is characteristically flattened in FAS.
2. Thin vermilion – thinned upper lip.
3. Small palpebral fissures – decreased eye width.

Alcohol-Related Birth Defects

The effects of alcohol exposure on the fetus can cause many more both defects that are not diagnostic criteria for FAS. These include heart murmurs (most commonly ventricular septal defect), joint position and functional abnormalities including small distal phalanges, kidney abnormalities (such as aplastic, dysplastic, or hypoplastic kidneys), and optic nerve hypoplasia that can lead to reduced visual acuity (Institute of Medicine 1995).

Mechanism of Alcohol Teratogenicity

The teratogenic effects of alcohol on the fetus are obviously a cause for concern. The reason for its adverse effects is due to the interactions between ethanol's pharmacology and the fetal physiology. Ethanol is known to diffuse from the mother's bloodstream, through the placenta, and into the

fetal compartment. Here, ethanol has a slower elimination compared to the mother and accumulates in the amniotic fluid. The enzymatic differences between mother and placenta also contribute to the teratogenic effects of ethanol as its metabolism lends to production of more toxic metabolites. Therefore, alcohol has a prolonged and dangerous effect on the fetus which is an especially vulnerable structure when developing (Gupta et al. 2016).

Conclusion

Alcohol is a known teratogen. Its effects on the fetus are varied and damaging. This is mediated through numerous mechanisms related to prolonged exposure and harmful metabolism of alcohol in the fetus. It can lead to a range of presentations, the most dangerous of which is FAS. This is characterized by growth retardation, CNS damage, and craniofacial abnormalities.

Definition

A steroid hormone present in various species, often in much greater quantities in males than females. In evolutionary psychology and endocrinology, testosterone is thought to play a key role in mediating life history trade-offs.

Introduction

Testosterone is a steroid hormone involved in many bodily processes, including reproductive physiology (e.g., spermatogenesis), morphology (e.g., development of secondary sexual characteristics), psychology (e.g., sexual desire), and behavior (e.g., aggression)—each of which plays an important role in survival and reproduction. Testosterone effects clearly manifest during puberty when its levels rise significantly. However, after puberty, short-lived testosterone fluctuations continue to affect some of these processes (e.g., aggression and sexual desire). Such

fluctuations take place in response to environmental inputs, including changes in temperature, interactions with potential mates, and competitive exchanges. This entry will provide an overview of testosterone by briefly discussing its history and mechanisms (e.g., production, action), followed by a review of theoretical and empirical approaches to understanding how it may be implicated in behavioral processes that are critical to fitness optimization.

History and Mechanisms

The discovery of testosterone's role in understanding behavior is often traced back to one of the first experiments in the field of behavioral endocrinology, published in 1849. In his work, Arnold Berthold castrated two roosters and demonstrated that the removal of the testes suppressed the development of secondary sexual characteristics (e.g., the comb and wattle), aggressive behavior toward other males, and crowing. Interestingly, Berthold castrated two other roosters and found that by reimplanting one testis in the abdominal cavity of each bird (with vascular and neural connections severed), the birds managed to develop the typical characteristics of an intact rooster (e.g., crowing, growth of combs, engaging in confrontations). Because the testes continued to function normally despite being detached from vascular and neural connections, Berthold concluded that the testes must secrete some chemical that influences morphological development and behavioral functioning. Berthold had just discovered testosterone.

Through several enzymatic steps, testosterone is synthesized from cholesterol in numerous tissues, including the testes, ovaries, and adrenal glands. Testosterone secretion is ultimately governed by the hypothalamic-pituitary-gonadal (HPG) axis. In men, testosterone secretion results from a hormonal "cascade," where the pulsatile release of gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates luteinizing hormone (and follicle-stimulating hormone) from the anterior pituitary gland, which in turn stimulates testosterone pulses from the

Leydig cells in the testes. In women, testosterone is primarily secreted in the ovaries, which contain cells similar to those of the testes.

Regardless of where it originates, testosterone acts on target cells through genomic and non-genomic mechanisms. Genomic mechanisms refer to the ability of unbound testosterone to cross the cell membrane, bind to the androgen receptor found in the cytoplasm of the cell, and migrate to the nucleus, where gene transcription can be activated or repressed. Once in the cell, testosterone can also be converted to other sex steroids, such as estradiol (via enzyme aromatase) or dihydrotestosterone (via enzyme 5- α -reductase), which in turn bind to steroid hormone receptors and affect cell functioning. Genomic mechanisms are considered "slow," meaning that the effects of testosterone take longer to manifest (e.g., >30 min, up to hours, or even days). Non-genomic mechanisms, on the other hand, are rapid effects (e.g., <30 min) that do not involve gene transcription but instead an interaction between testosterone and cell membrane receptors (e.g., GABA_A receptors).

Testosterone and Life History Theory

In evolutionary biology, life history theory refers to the resource trade-offs faced across the lifespan by species trying to maximize reproductive fitness. The premise of life history theory is that resources (e.g., energy, time, nutrients) are limited, and thus when they are invested into one trait to promote fitness, there is less available to invest in other fitness-promoting traits. Testosterone plays a key role in mediating some of the behavioral, physiological, and morphological processes that are inherent to life history trade-offs, such as copulation and courtship, sperm maturation, muscle growth and maintenance, immune function, and metabolism (Hau and Wingfield 2011).

Mating Versus Parenting Trade-Off

One of the most studied life history trade-offs thought to be mediated by testosterone is mating

effort versus parenting effort. Seminal work by John Wingfield (i.e., “The Challenge Hypothesis”; see Wingfield 2017, for review) found seasonal fluctuations of testosterone in avian species. While androgen levels were the lowest during the nonbreeding season, their levels rose at the start of the breeding season. This increase in testosterone was necessary to promote spermatogenesis, the expression of secondary sexual characteristics, and reproductive behavior. During the rest of the breeding season, androgens reached a physiological maximum in response to intrasexual encounters that birds had to face when protecting their territories. One important finding from Wingfield’s work was that the expression of paternal care required temporary decreases in testosterone secretion, providing preliminary evidence for testosterone’s role in mediating mating versus parenting trade-offs.

Following from Wingfield’s work in avian species, research in humans showed that testosterone levels vary as a function of relationship and fatherhood status. For example, Gettler et al. (2011) followed a large sample of men ($N = 624$) for nearly 5 years and examined the extent to which partnering (i.e., married or cohabitating), fatherhood, and paternal caregiving were prospectively associated with testosterone levels. Single and childless men with elevated morning testosterone levels at the beginning of the study were more likely to become newly partnered and newly partnered with children 4.5 years later. Further, men who became newly partnered with children by follow-up showed a greater decline in testosterone from the beginning to the end of the study, when compared with men who remained single and childless throughout the study. Additionally, a comparison of childcare investment showed that fathers who were most involved in the care of their children had significantly lower testosterone at the end of the study than fathers who did not participate in offspring care. Other studies showed that men with higher testosterone tend to experience less satisfactory romantic relationships and higher rates of divorce, while lower testosterone levels have been associated with greater parental involvement (reviewed in Roney and Gettler 2015; see also Zilioli and Bird in press). These

shifts in testosterone may be adaptive: on one hand, reduced levels may promote investment in successful relationships with close others (e.g., less risk of defection, greater care, and likelihood of offspring survival) and, on the other hand, elevated concentrations may promote behavior aimed at securing mates (e.g., mate seeking, extra-pair desires).

Basal (i.e., at rest) levels of testosterone have been found to map onto traits inherent to reproductive success; however, testosterone concentrations are not static. On the contrary, testosterone fluctuates quite rapidly in response to environmental inputs and in patterns that are consistent with the predictions of the life history theory. Specifically, it has been hypothesized that situations involving mating effort directly (such as interactions with a mate) or indirectly (such as intrasexual competition) lead to an increase in testosterone, while interactions involving parenting effort (such as nurturant parent-offspring interactions) lead to suppressed testosterone release or a testosterone decline (Zilioli and Bird in press). Empirical evidence indicates that testosterone is released both in anticipation and in response to competitions (see Carré and Olmstead 2015), in response to mating-relevant stimuli (reviewed in Roney and Gettler 2015), and drops following nurturant interactions with offspring (Kuo et al. 2016). Importantly, these rapid changes in testosterone to various social stimuli (competition, mating, parenting) seem to map onto future behaviors in these same domains. For example, testosterone responses to competition influence the decision to compete again, future competitive performances, aggression, risk-taking, and courtship behaviors (Carré and Olmstead 2015; Zilioli and Bird in press).

How testosterone is influenced by and influences social behaviors can be modified by situational, motivational, and physiological factors. In other words, the *strength* or *direction* of the bidirectional relationship between testosterone and social behavior changes as a function of *moderators*. Briefly, situational moderators refer to external factors that are not easily controlled, such as winning or losing a competition, with experiences of social victory being associated with an increase

in testosterone relative to losing (see Mazur 1985, for this prediction from the “Biosocial Model of Status”; see Geniole et al. 2017, for meta-analysis). Motivational moderators refer to individual differences in psychological variables such as personality (e.g., dominance) or mating preferences (e.g., sociosexual orientation). Finally, physiological moderators refer to the interaction of testosterone with other hormones and signaling molecules, such as cortisol, which has been found to attenuate the relationship between testosterone and behavior (see Mehta and Prasad 2015, for review of this “Dual-Hormone Hypothesis”).

Conclusion

As briefly reviewed, testosterone is implicated in numerous processes that are critical to reproduction and survival, including the expression of secondary sexual characteristics, mate seeking, aggression, and status seeking. From an evolutionary perspective, testosterone’s role in promoting reproductive fitness can be explained largely from the framework of the life history theory, which proposes that species face evolutionary trade-offs (e.g., mating versus parenting) due to the limited availability of resources (e.g., energy, time). Some of these trade-offs are mediated by testosterone. Future work in evolutionary endocrinology and psychology will be needed to shed light on the situational, motivational, and physiological moderators of the relationship between (1) basal testosterone and behavior, (2) exposure to social stimuli and acute testosterone release, and (3) acute testosterone release and social behavior.

Definition

The capacity to predict and interpret behavior by using representations of hidden, causally efficacious mental states.

Introduction

“Theory of mind” consists in the ability to use concepts of intentional mental states, such as beliefs, emotions, intentions, goals, and perceptual states, in order to predict and interpret behavior. Functional magnetic resonance imaging studies have revealed a distinctive network of neural regions that is active during theory-of-mind tasks, including the temporal-parietal junction, the posterior superior temporal sulcus, the medial prefrontal cortex, the precuneus, and the temporal poles (Van Overwalle [2009](#)). Deficits in theory-of-mind abilities, which are common in autism spectrum disorder (Tager-Flusberg [2007](#)), typically correlate with broader difficulties in social understanding.

Many scholars have suggested that theory of mind is an innate adaptation for social cognition, emerging very early in development and playing a crucial role in social learning and the acquisition of language (Baron-Cohen 1997). However, others have argued that theory of mind is the product of largely domain-general learning processes and is acquired gradually over the course of development through social experience (Wellman 2014). A third view argues that humans possess two systems for theory of mind: an innate, domain-specific “implicit” system and a learned, domain-general “explicit” system (Apperly and Butterfill 2009).

The False-Belief Task Controversy

The classic experimental paradigm for testing theory-of-mind abilities in children is the false-belief task (Wimmer and Perner 1983). In the most common version of this task, participants observe an agent place an object in a box and then leave the room. While the first agent is gone, a second agent moves the object to another hidden location. When the first agent returns, the participant is asked to predict where the agent will look for the object (or in some versions of the task, to say where she thinks the object is). The correct answer is “in the box.” In order to pass the task, the participant must represent that the agent has a *belief* about the location of the object that differs from what is really the case and use that representation to accurately predict what she will do next. Similar tasks test the capacity to reason about other mental states, including desires, states of knowledge, perceptual access, and emotions (Wellman and Liu 2004).

Typically, children fail the false-belief task until after their fourth birthday, as do many adults with autism spectrum disorder (Wellman et al. 2001). Since these results were first discovered, there has been controversy over their interpretation. “Constructivists” have argued that children’s shifting performance on this task reflects the emergence of a new concept of *belief*, amounting to a fundamental change in children’s intuitive theory of the social world, analogous to theoretical changes brought on by scientific discovery

(Gopnik and Wellman 1992). Children, in other words, are learning what beliefs are and the circumstances in which people have them. “Nativists,” in contrast, have pointed to the selective deficits on the false-belief task displayed by people with autism spectrum disorder as evidence of an underlying theory-of-mind module, which is selectively impaired in autism (Baron-Cohen 1997). Nativists also argue that younger children’s difficulties on the false-belief task don’t reflect the absence of a concept of belief but rather a performance error due to the immaturity of their domain-general executive capacities. According to this view, the concept of belief is innate, but children can fail to deploy it successfully in certain experimental contexts. Importantly, the nativist view doesn’t have to claim that theory of mind is unaffected by experience and individual learning. Rather, the claim can be that these changes are both constrained and facilitated by a domain-specific, innately channeled, learning mechanism that comes equipped with a few basic mental-state concepts (Carruthers 2015).

Two Views on the Evolution and Development of Theory of Mind

In the background of the nativist approach is a theoretical commitment concerning the importance of theory of mind in the evolution of human social intelligence. On this view, innate adaptations for theory of mind are thought to have emerged early in the hominid line. In the highly social environments of ancestral hominids, accurate prediction and interpretation of the behavior of conspecifics would have been crucial for survival. Accounts of the earliest emergence of theory-of-mind abilities in primates emphasize the adaptive importance of theory of mind in social competition, deception, and manipulation, as individuals sought to gain mating opportunities and to improve their status within their group’s social hierarchy (Byrne and Whiten 1988). This “Machiavellian intelligence” hypothesis is supported by evidence that modern great apes seem to demonstrate at least simple forms of theory-of-mind abilities in competitive but not cooperative experimental contexts (Call and Tomasello 2008).

Accounts of the evolution of more highly developed, and perhaps specifically human, theory-of-mind abilities, in contrast (including capacities to reason about the false beliefs of others), tend to place greater emphasis on the cooperative functions of theory of mind, particularly when coordinating multiple agents in the pursuit of mutually shared goals, such as group hunting and foraging (Tomasello 2014). Inferences about beliefs and intentions are also thought to have played a crucial role in the emergence of early systems of gestural communication, such as pointing and pantomime, which require inferences about mental states on the part of both the communicator and the audience (Scott-Phillips 2014). These cooperative environments are thought to have created an adaptive feedback loop, where selection pressures for more complex theory-of-mind abilities led to more complex forms of cooperation, which created further selection pressures on our theory of mind. Thus, theory of mind is thought to have fueled the evolution of highly complex forms of mutualistic cooperation, in addition to supporting the development of these same social abilities in ontogeny.

Constructivists typically accept that human beings possess some special adaptations for social intelligence but generally deny that these amount to a genuine theory of mind. For example, some constructivists acknowledge that neonates are innately biased to attend to faces and eyes and are innately disposed to engage in imitative behavior (e.g., Meltzoff 2007). According to constructivist accounts, these low-level, noncognitive mechanisms serve as a scaffold for children's early theory-of-mind development by directing their attention toward socially relevant phenomena. The latter then serve as inputs for domain-general learning procedures, such as statistical learning (Ruffman et al. 2012). Many constructivists also believe that children's acquisition of a mature theory of mind depends on exposure to specific linguistic inputs, such as clausal complementation syntax or mental-state vocabulary (e.g., de Villiers and Pyers 2002). Thus, while nativists posit that the ancestral emergence of domain-specific cognitive adaptations for theory of mind made complex forms of cooperation and linguistic

communication possible, constructivists hold that the existence of complex cooperative environments lay the developmental foundation for children to acquire a theory of mind via individual learning, which implies that it is an evolutionarily recent, culturally dependent phenomenon (Heyes and Frith 2014).

Does Theory of Mind Emerge Early or Late in Development?

Support for the constructivist view comes from evidence that theory-of-mind development is influenced by both social experience and language. For instance, having older siblings tends to lead to earlier success on the false-belief task, as do greater amounts of parental mental-state discourse (Ruffman et al. 2012). Strikingly, deaf children who do not learn sign language until later in life also have persistent difficulties on the false-belief task, even in adulthood (Pyers and Senghas 2009). These findings seem incompatible with the nativist's performance-error account of children's performance on the false-belief task, suggesting instead that children's social and linguistic environment plays an important role in determining their theory-of-mind abilities.

In response to these findings, some nativists have argued that they reflect the fact that children must learn how to *apply* their innate theory-of-mind abilities in different social and linguistic contexts and that variations in social environment impact this learning process (Westra 2017). In effect, the suggestion is that younger children fail at the tasks because their grip on discourse pragmatics is weak, leading them to misunderstand the point of the questions they are asked, and it is this that is impacted by social experience.

In support of the nativist view, a large body of evidence has emerged more recently, demonstrating a range of theory-of-mind abilities in children in the first 2 years of life, well before they pass verbal forms of the false-belief task. For example, a number of studies have adapted the classic false-belief task to make it suitable for infants. Importantly, these tasks never ask children to make explicit, verbal predictions. Instead, they rely on

children's spontaneous behaviors to measure their theory-of-mind abilities. For example, one such task presented 15-month-olds with a scene in which an experimenter hid an object in one of two boxes and then left. While the experimenter was absent, the object was moved to the other box. When the experimenter returned, infants either saw her reach toward the first, empty box, or the second box, where the object then was. Results show that infants look far longer when the experimenter reaches for the second box, suggesting that they find this behavior surprising (Onishi and Baillargeon 2005). The infants were seemingly expecting the agent to reach into the box where she *believed* the goal object to be.

Researchers have also designed ways of testing early false-belief competence by exploiting the fact that young children are highly motivated to help other people achieve their goals (Buttelmann et al. 2009). In these tasks, 18-month-olds observe an experimenter place a toy in one of two boxes and close the lid. The experimenter then leaves the room, and the children see a second experimenter move the toy from the first box to the second box. Then the first experimenter returns and begins to struggle with the lid of the first box. The authors predicted that if children understood that the experimenter desired the toy but had a false belief about its location, they should respond by retrieving the toy from the second box. In a true-belief control task in which the first experimenter observes the location change, in contrast, children should instead help the experimenter open the first box, presuming that she must want something inside it. Indeed, this is what they found.

The interpretation of these results, like those of the original false-belief task, has been a subject of great controversy. While nativists have used infant false-belief paradigms to support the claim that the capacity for representing beliefs is innate (Baillargeon et al. 2010), critics of these paradigms have offered various alternative, low-level explanations of the same findings. According to some of these interpretations, infants' successful performance on these tasks may not reflect an abstract concept of belief but rather the tracking of statistical regularities in observable behavior (Ruffman et al. 2012). Nativists have responded

to these criticisms by pointing out that these alternative explanations have tended to be post hoc and have failed to issue in new data (Scott 2014). The nativist framework, in contrast, has generated a continuous stream of new results, employing an ever-widening set of experimental paradigms. However, these debates are currently ongoing.

Can Apes Pass False-Belief Tasks?

We noted in the section "[Two Views on the Evolution and Development of Theory of Mind](#)" that there is evidence that other great apes have at least a simple form of theory of mind, one that allows them to track and reason about the goals and states of knowledge or ignorance of other agents. But until recently, all tests for false-belief understanding in other primates had proven negative (Call and Tomasello 2008). Recently, however, researchers have successfully adapted for use among primates some of the methods for testing false-belief competence in young children, with striking results. In one study, the experimenters showed chimpanzees, bonobos, and orangutans videos depicting an interaction between an actor dressed as a zookeeper and an actor dressed as a gorilla. The videos began by showing the gorilla hitting the zookeeper and then running into one of two haystacks arrayed at either side of the screen. While the zookeeper turned away to fetch a stick (which, in familiarizations, was used to hit the haystack containing the gorilla), the gorilla moved from one haystack to the other. Then the zookeeper turned around with the stick raised, poised to attack. The researchers used an eye tracker to measure whether the apes would look in anticipation toward the actual location of the gorilla or to the location where the zookeeper will think the gorilla is hiding (i.e., anticipating and reasoning from the zookeeper's false belief). The results showed that all three species of ape looked reliably more toward the false-belief location, suggesting that they were indeed tracking the zookeeper's beliefs (Krupenye et al. 2016). In another study, researchers adapted the active helping design of Buttelmann et al. (2009) (see above) for use with chimpanzees, bonobos, and

orangutans. They, too, found that great apes seemed to use information about false beliefs in order to help an experimenter retrieve an object from a locked box (Buttelmann et al. 2017).

Some critics have argued that these results, like the infant false-belief-task results, should not be interpreted in rich, mentalistic terms; instead, we should prefer explanations that only attribute to apes the ability to make predictions about behavior based on low-level, observable regularities, such as the appearance and disappearance of the colored shirt of the zookeeper (Heyes 2017). To test this hypothesis, Krupenye and colleagues designed a control task that matched their original anticipatory looking paradigm but replaced the actors with inanimate colored shapes (Krupenye et al. 2017). They found that, in contrast to the task involving actors, the participants were no more likely to look toward either target location when observing the same interaction between inanimate shapes. This provides compelling evidence that the apes' predictive gaze behavior was specifically sensitive to the social nature of the stimuli, as opposed to its low-level properties. All of these results are, however, quite recent, and further research is necessary before conclusions can confidently be drawn.

Thus, two recent studies seem to show that three other species of great ape are capable of passing false-belief tasks. This result, if it is valid, has striking implications for the debate about the language dependence of theory of mind. If nonlinguistic primates are able to represent beliefs, this casts serious doubt on the claim that such an ability requires linguistic experience, or is uniquely human. These findings also suggest that belief representation may in fact be evolutionarily quite ancient and potentially shared by the last common ancestor of humans, chimpanzees, bonobos, and orangutans.

Such inferences should be drawn cautiously, however: the presence of robust theory-of-mind ability in modern great apes does not necessarily imply that it is an innate adaptation. For it is possible that these apes acquired their abilities through individual learning (and hence that ancestral apes might have done so as well). In other words, even if great apes do reason about false

beliefs, this doesn't necessarily provide support for nativism about theory of mind in human beings. What it does do, however, is undermine the claim that false-belief understanding is specifically dependent on either *linguistic* experience or experience of distinctively human forms of collaboration and joint action.

The two-Systems View

Another set of theorists has attempted to resolve the dispute between nativists and constructivists by proposing an ecumenical solution that incorporates both constructivist and nativist elements (Apperly and Butterfill 2009). According to these "two-systems" accounts, infants' early competence on "implicit" false-belief tasks (and by parity of reasoning, the recent successful performance of other great ape species on similar tasks) does reflect a domain-specific adaptation for tracking mental states. This "implicit" theory-of-mind system is said to be fast, effortless, automatic, and largely encapsulated from executive systems; it also persists unchanged into adulthood and is shared with our nearest primate relatives. Thus, in many respects this implicit mindreading system resembles the kind of domain-specific adaptation posited by nativists. However, two-systems theorists hold that due to its automatic and encapsulated architecture, the implicit mindreading system is subject to "signature limits." In particular, while it can represent beliefs about the *locations* of objects (e.g., "Bill believes that the apple is in the box"), it cannot handle beliefs about the *identity* of objects (e.g., "Bill believes that the apple is really a pear"). This is because the implicit system is thought to *track* beliefs and other mental states without representing them as such and, in particular, without representing the aspectual nature of belief states. (Famously, one can believe that Jocasta is beautiful without believing that one's mother is beautiful, even though Jocasta is in fact one's mother. Here one and the same person is thought about under two different aspects.) The implicit system cannot, therefore, fully capture the richness and flexibility of the mature concept of belief.

In humans, one of the functions of the implicit system is to scaffold the acquisition of a second, parallel, explicit theory-of-mind system that develops much more gradually. This system is said to be slow, effortful, and heavily reliant upon executive resources, such as working memory. It develops gradually via domain-general learning in response to social and linguistic input and only emerges after children's fourth birthday (thus enabling them to pass the explicit false-belief task). Unlike the implicit system, this one isn't subject to signature representational limits. However, because it relies heavily on working memory, it must be directed by top-down goals and is compromised under cognitive load. The explicit mindreading system closely resembles the conception of mindreading posited by constructivists, albeit supported by a relatively more complex set of domain-specific cognitive adaptations. Thus, by adulthood, human beings are said to possess two parallel theory-of-mind systems, each with a distinct information-processing profile.

To test the prediction that the implicit mindreading system is subject to signature limits, two-systems theorists have compared adults' and young children's implicit theory-of-mind predictions in scenarios where agents have false beliefs about either an object's location or its identity (Low and Watts 2013). To test participants' ability to track false beliefs about identity, the experimenters constructed a scenario in which participants were familiarized with an agent who demonstrated a consistent preference for a certain color, always reaching for blue items rather than red items, for example. Next, out of sight of the agent, participants were familiarized with a paper cutout figure that appeared as a red robot from one side and as a blue robot on the other. They then watched as the agent observed what she would have seen as a blue robot enters one of two boxes. Next, unbeknownst to the agent, the figure rotated 180° and moved to the second box while presenting to the agent as a red robot. Because the agent didn't know that the red and blue robots are the same individual, she should believe that there was still a blue robot in the first box. Thus, if participants were tracking beliefs about identity, they should expect the agent to reach toward the first box. However, neither adults

nor children reliably looked in anticipation toward the first box, suggesting that they were insensitive to the agent's beliefs about object identity. Meanwhile, both groups showed correct anticipatory looking on the control task that only involved beliefs about the object's location.

These results provide support the claim that while implicit theory of mind accurately tracks beliefs about the locations of objects, it doesn't track beliefs about the identities of objects. However, critics of this study and others like it have pointed out that the object-identity task, which involves effortful forms of mental rotation, is likely to place additional demands on executive function that are not present in the object-location control task. This makes it unclear whether the relevant failure is due to signature limitations on implicit theory of mind or rather limitations on working memory (Carruthers 2015). It is therefore unclear whether this evidence truly supports a two-systems view. Nevertheless, two-systems accounts of theory of mind have significantly influenced debates about the cognitive architecture of our social cognition abilities.

Conclusion

As can be observed in the debate about the false-belief task, there is considerable disagreement in the literature about the role of theory-of-mind abilities in socio-cognitive development: while nativists believe that theory-of-mind is a basic adaptation that plays an important role in early social learning, constructivists hold that theory of mind is itself the *product* of social learning. These views correspond to distinct narratives about the emergence of theory of mind in the hominid line: if the nativist view is right, then theory of mind is evolutionarily ancient; if the constructivist view is correct, then it is likely to be a far more recent phenomenon. The two-systems view attempts to carve a middle ground between these two camps, allowing that some aspects of theory of mind are indeed evolutionarily ancient and early developing, while others are evolutionarily novel and acquired via social learning. However, the evidence in favor of this view is itself a source of controversy.

Theory of Mind and Evidence of Brain Modularity

Definition

Theory of Mind (ToM) refers to one's cognitive ability to ascribe and regard the mental states of others. Brain modularity refers to the theory that at least some cognitive functions are facilitated by innate neural structures that have been honed and selected through evolution.

Introduction

The term *Theory of Mind* was coined in 1978 by David Premack and Guy Woodruff during their investigation into the capacity of a chimpanzee to “impute mental states,” an ability previously considered to belong solely to the human race (Premack and Woodruff 1978). Since then, countless studies have tested various aspects of ToM ability, and while the existence of such abilities are accepted nearly ubiquitously across the scientific community, the underlying mechanism allowing for ToM remains a point of contention.

Theory of Mind

The ability to compute the mental states – beliefs, desires, knowledge, goals, etc. – of others varies from person to person. Predicting other's behavior using not only physical and visual stimuli but also inferences of such mental states is a skill that develops through time. In 1983 Heinz Wimmer and Josef Perner conducted a study in which

children observed a boy place chocolate in a blue cupboard and then leave the room. While the boy is out, his mother moved the chocolate to a green cupboard. Upon the boy's return, the studies' participants were asked where the boy would look for the chocolate. Eighty-six percent of 6–9 year-old children correctly guessed that the boy would look in the blue cupboard, where he had left it, while 100 % of the 3–4 year-old participants answered that the boy would look in the green cupboard, where the chocolate actually was, even though they knew the mother had moved it without the boy's knowledge. Thus, Wimmer and Perner were able to conclude that ToM ability develops over time, and children under 4 years old likely don't have the ability to predict other's behavior when it requires an understanding of their propositional attitudes (Wimmer and Perner 1983).

The Modularity-Nativist Approach

The concept of modularity became widely popular upon Fodor's publication of *The Modularity of Mind* in 1983, in which he proposed that certain lower mental functions are the result of innate, domain-specific brain structures (modules), analogous to organs, which are relatively isolated and in turn feed into a domain-general central engine (Fodor 1983).

More recently, however, Carruthers made his case for massive modularity, claiming that the entirety of the brain is comprised of a hierarchy of such modules, each responsible for separate mental functions. As evidence for his theory, Carruthers discussed the ability of various brain injuries to hinder certain cognitive functions while leaving others intact (Carruthers 2006). The Modularity-Nativist Approach to Theory of Mind ability relies on this proposed architecture, and the most convincing evidence for it follows Carruthers' train of thought. Simon Baron-Cohen, in 2001, published a review of the cognitive abilities of autistic children which highlighted a relative inability to pass first- and second-order false belief tests, even when other cognitive functions are more developed (Baron-Cohen 1991).

Conclusion

Theory of Mind refers to one's ability to attribute mental states to others and regard them in relation to one's own. Of the different theories attempting to explain ToM, the argument from modularity is of particular interest to evolutionary psychologists, crediting innate neural structures developed through natural selection as the foundation for mentalizing ability.

Synonyms

[Mental state attribution](#); [Mindreading](#); [Social cognition](#)

Definition

The cognitive ability to predict or explain an individuals' behavior through the attribution of mental states.

Introduction

Comparative cognition researchers have long been interested in the nature of nonhuman animal social capacities. One capacity has received prolonged attention: mindreading, or “theory of mind” as it's also called, is often seen to be the ability to attribute mental states to others in the service of predicting and explaining behavior. This attention is garnered in no small measure from interest into what accounts for the distinctive features of human social cognition and what are the evolutionary origins of those features. This entry surveys: (1) main hypotheses concerning the adaptive value of mindreading, (2) theoretical problems complicating our ability to determine whether nonhuman animals mindread, and finally (3) proposals that mindreading is a plural rather than unitary cognitive system.

Social Intelligence Hypothesis

One intuitive idea is that mindreading evolved in response to social pressures. The Social Intelligence Hypothesis asserts that the ability to reason about the intelligent action of group members affords greater benefits as social settings become more complex (Humphrey 1976; Jolly 1966). Certain social groupings seem to require substantial cognitive control on behalf of group members. Individuals must potentially be able to recognize and track particular individuals, kin relationships, and dominance hierarchies, all of which are subject to rapid changes over time. The Social Intelligence Hypothesis holds that social environments are necessary conditions on the development of social cognitive skills like mindreading. To substantiate this hypothesis, it is important to determine whether nonhuman animals that lack the complexity of social groupings seen in similar species also lack analogous social cognition skills

(Vonk et al. 2015). For instance orangutans, which are relatively solitary in relation to other great apes, are sufficiently similar with regards to social cognitive skills (Herrmann et al. 2007).

Exactly what social cognition skills were selected for is a further question. The ability to reason about others' behavior in social contexts might be useful in out-competing conspecifics. Known under the guise of the "Machiavellian hypothesis," some argue making better predictions of others' future behavior allows for one to manipulate others through various forms of deception (Whiten and Byrne 1988). As individuals gain more sophisticated understanding of social action and greater predictive success, competition becomes tough, thus creating an evolutionary "arms race." This hypothesis interprets the coalition formation and reconciliation behavior found in many primates in terms of long-term strategic responses, though there may be more mundane reasons, such as tracking food locations that promote this behavior (see Barrett and Henzi 2005).

An alternative view, one commensurate with Alison Jolly's initial account, suggests that cooperative social learning, not competition among conspecifics, led to the development of sophisticated social cognitive skills such as mindreading (Andrews 2012a; Heyes and Frith 2014). Social learning is the transmission of information across group members within a social context. While mindreading ability may not be required to engage in forms of social learning in mimicry and imitation, other social cognition skills may be required. For example, imitation might require that agents have (i) a "natural pedagogy" or evolved interpretive biases towards demonstrators and (ii) take a teleological stance, i.e., attribute purpose, design, or function, to others (Csibra and Gergely 2005). Some comparative evidence suggests that over-imitation, or the tendency to imitate demonstrators' behaviors in spite of their causal irrelevancy, is a distinctively human strategy facilitating more rapid social learning of instrumental skills and social conventions (Horner and Whiten 2004). It has been hypothesized then that our species-specific proclivity for high fidelity imitation may be linked to "cumulative cultural transmission": instrumental skills and social conventions are not

only inherited across generations – imitated behaviors may be recombined in novel contexts and in innovative ways (Legare and Neilsen 2015).

The Logical Problem

It is widely held that reasoning about the intentional actions of others is a form of causal reasoning – we attribute unobservable causal determinants of others' behavior in intentional explanations just as we do when we discover what makes simple machines function. This view receives partial support from developmental research on causal reasoning. Alison Gopnik and her colleagues introduced young children to boxes called "blickets" that would light up or make a sound under various parameters, such as when some collection of objects and the device were in direct contact (Gopnik and Sobel 2000). They concluded that not only did children recruit memories of prior interactions when being asked to predict what would make the blicket work, they were sensitive to the potential causal mechanisms at work. While in many cases causal reasoning requires knowledge of the observable states of objects at different times, it sometimes requires the positing of intermediate states that are perceptually opaque yet causally relevant in the assessment of observed events. The perceptually opaque causal determinants in the case of mindreading are internal mental states – the beliefs and desires or perceptions and goals that cause the resultant behavior.

Comparative researchers disagree about the causal reasoning abilities of nonhuman animals. While Penn and Povinelli (2007) claim studies suggest that chimpanzees do not share proficiency at inferring the underlying causal structure of phenomena with humans, other researchers have found evidence of causal reasoning in great apes on a par with that which we find in human children. Völter and Call (2014) show that apes infer causal structures from the coactivation of blicket detectors similarly to young children and can recruit this knowledge in their interventions.

Assuming mindreading is analogous to causal reasoning in the way hinted above, there is further

disagreement as to whether nonhuman animals' social cognitive abilities call upon unobservable intentional states. While evidence suggests that subordinate chimpanzees know what dominant chimpanzees observe when competing over a food source (Hare et al. 2000), whether their behavioral preferences involve the attribution of mental states is hotly contested. Povinelli and Vonk (2003) take issue with these and similar findings, on the grounds they are subject to "the logical problem". Assume we are deciding between two hypotheses regarding a subjects' behavior in a social context. The mindreading hypothesis assumes the subject confers mental states on some conspecific in the service of predicting their future behavioral states. The competing behavior reading hypothesis assumes she confers only behavioral states. If we are limited to the subjects' behavior when deciding between these two hypotheses, it seems just as likely that the subject relies on associations between observable behaviors in predicting the future states of conspecifics as it does that they would rely on the unobservable mental states.

Exactly what the logical problem means for comparative research and whether it can be solved is up for debate. Tomasello and Call (2006) argue that mindreading hypotheses provide the best explanation since they unify a range of very different experiments already demonstrated. Others, while not so sanguine, are hopeful that a novel experimental design could solve the problem (e.g., Lurz 2012; Heyes 2015; Sober 2015, and Bugnyar et al. 2016). Halina (2015) argues that the logical problem is not a unique theoretical dilemma for comparative researchers, so there is no special epistemic burden with regards to disproving competing behavior reading hypotheses. Andrews (2012b) similarly suggests that the logical problem is an ancillary of the philosophical problem of other minds: what justifies my attributions of mental states to others, given that my access to their mental life is always mediated through their behavior? Buckner (2014) evinces that in order to solve the logical problem, there must be a unique causal role for the contents of an agent's mental states to play in determining their action. But which interpretations of the content of

internal mental states are causally efficacious, and how so? Because any observable behavior is compatible with a potentially infinite set of mental attitudes, accurate attribution that would facilitate causal reasoning about observable actions of others appears to be computationally intractable (Zadwizki 2014).

Multiple Systems Hypothesis

Just as one might distinguish between an agent's explicit, reflective, deliberate knowledge from their implicit, heuristic-based, automatic knowledge of the causal structure of some physical system, we might discover multiple processing systems for mindreading. Children can correctly verbally identify and track false beliefs at around 4 years of age. Even though some nonhuman animals consider others' perceptual perspectives, this ability is not on par with children's ability to verbally reason about others' beliefs. That said, testing false belief responsiveness by measuring preferential looking times has some now thinking that preverbal infants have mindreading skills as well (Onishi and Baillargeon 2005). Infants' surprising performance in social contexts means could help make sense of the ontogeny and phylogeny of social cognition. Some conjecture that mindreading is not a unitary process, but rather can be decomposed into unique social cognition skills that have divergent evolutionary and developmental trajectories.

Partial evidence for these views comes from variations in reaction times in belief attribution.

By comparing performance across species and developmental stages, researchers aim to identify "signature limits" which reveal the contours of mindreading abilities (Butterfill and Apperly 2013). Signature limits indicate restrictions on the performance of some relevant tasks and can help to illuminate the mechanisms involved in performing the task (Thompson 2014). For example, while we require additional processing to report on someone's belief; it takes longer to answer questions about a person's belief than it does to answer factual questions about the situation (Back and Apperly 2010). Perspectival

information is different; perceptual information about others' point of view are automatically processed by subjects (Samson et al. 2010). These studies suggest that adults' judgments about the number of objects they could see in a visual scene were slower and more error-prone when the scene contained an irrelevant agent whose visual perspective was different, suggesting that another perspective can cause an indicative interference effect.

If mindreading was not a unitary cognitive system in humans, then nonhuman animal social skills may mirror some aspects of human capacities and not others. Still there are other ways of interpreting limitations on subjects' performance that do not necessitate the ascription of multiple processes. Subjects' performance limitations could be the result of limitations on domain general capacities such as working memory (Carruthers 2016) or infants' preferential looking times may be the result of implicit memory of the visual contact between the agent and the objects and experience with this sort of behavior (Perner 2016).

Conclusion

Investigations into the social cognition skills of nonhuman animals has profited from the prolonged interaction between researchers in developmental psychology, neuroscience, ecology, anthropology, and philosophy. Above we focus on the development of research with regards to mindreading or the ability to reason about others' mental states in the service of predicting and explaining their behavior. Importantly we see the question of what is the nature of mindreading and what is its adaptive value occur in a parallel, piecemeal fashion.

Kohlberg's rationalistic theory; Moral development

Definition

Kohlberg's theory of moral development explains how moral development takes place in human animals.

Introduction

The nature and the cognitive and emotional determinants of moral judgment have been empirically studied since the emergence of the science of psychology. Although one of the first systematic theories began with Piaget (1965), the first systematic theory based on empirical research was introduced by Lawrence Kohlberg (1969). Kohlberg's theory is regarded as a rationalist theory since it assumes that the main determinant of moral judgment is rational thinking processes, even though it is thought that emotional or intuitive processes are also involved – at least in part – in moral judgment.

Kohlberg's Three Levels

There are three levels (in a total of six stages) in Kohlberg's theory of moral development in a hierarchical structure. These three levels follow a stable sequence but qualitatively correspond to different types of moral reasoning. The first and primary motivation of the first level

(pre-conventional morality), which includes the first two stages (obedience and punishment; individual interests), is to avoid punishment and attain pleasure. The individual at the first stage does not understand or care that other people can have similar wishes and desires besides their own desires. Thus, the person in this stage acts in an egoist manner. Then, in the second stage, the person realizes that she can differentiate her own desires from the wishes of other people and the authority figures. At the second level (conventional morality), which includes the third and fourth stages (interpersonal; authority), the individual has a motivation that is concerned with mutual relations and expectations. The main motivation of the individuals at this level is to be accepted and socially approved by others and, in this context, to fulfill the orders of those who are hierarchically superior. Therefore, at this level, people define interpersonal relations through their place in society. At the last and third level (the post-conventional morality), the individual develops an autonomous moral conception, while in moral judgment she often refers to a universal set of principles (such as justice and fairness). This stage corresponds to a universal set of moral principles that all people must follow, according to Kohlberg, and moral superiority is characterized as reaching this stage. The normative moral superiority, which a rational human being as in Kant's categorical imperative must achieve as a result of cognitive reasoning, is a sense of universal justice. The individual in this stage sees morality as an end, not as a means.

Assessing Morality

Kohlberg scores people's moral judgments based on how they justify their moral judgments in terms of these three levels (i.e., pre-conventional, conventional, and post-conventional moralities). For example, in the well-known Heinz dilemma, the participant reads the following moral vignette:

A woman was on her deathbed. There was one drug that the doctors thought might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to

make, but the druggist was charging ten times what the drug cost him to produce. He paid \$200 for the radium and charged \$2,000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about \$1,000 which is half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said: "No, I discovered the drug and I'm going to make money from it." So Heinz got desperate and broke into the man's laboratory to steal the drug for his wife. Should Heinz have broken into the laboratory to steal the drug for his wife? Why or why not?

According to Kohlberg, the decision of the participant regarding whether Heinz should or should not steal the drug has no theoretical significance. However, it is theoretically important as to how the participant justifies her moral judgment. Someone who says that Heinz should not steal the drug, because if he steals, he must be imprisoned (i.e., avoiding punishment), or Heinz should steal because if his wife lives he will make Heinz a happier person (self-interest) is scored as having pre-conventional morality. Someone who states that Heinz should not steal the drug because the legal rules prohibit it or that Heinz should steal the drug because his wife would expect him to be a good husband is scored as having conventional morality. Someone who says Heinz should steal the drug because everyone has the right to live or Heinz should not take the drug because others may need this medicine and everyone's life is equally important (i.e., universal human rights) is scored as having post-conventional morality.

According to Kohlberg (1971), moral development does not progress only with age (i.e., biological maturity); however, moral reasoning should be related to cognitive reasoning capacity. It has been found that the individuals who scored as having post-conventional morality showed higher performance in some tasks measuring cognitive reasoning (Kuhn et al. 1977). However, the theory of Kohlberg's moral development was later criticized by different theoretical perspectives (cf., Haidt 2001). It is thought that empathy capacity, rather than cognitive development (e.g., Hoffman 1993), may be an important factor in determining moral reasoning. However, Kohlberg (1981) actually believes that the ability to take perspective, a

cognitive capacity, is the fundamental determinant of moral reasoning.

Criticisms of Kohlberg's Theory

The theory of Kohlberg's (1969) moral development has been subjected to a number of criticisms from both theoretical and methodological perspectives. The most important theoretical criticism is the claim of universality of the hierarchical structure proposed by the theory. However, Turiel et al. (1978) showed that the basic assumptions of the theory were supported in a cross-sectional study. Likewise, Nisan and Kohlberg (1982) and then Colby et al. (1983) tested Kohlberg's theory and showed that most of the predictions were supported in a longitudinal design as well. But all of these studies have some certain limitations, such as being based on hypothetical dilemmas to measure moral judgment (see below).

In addition, the argument that rational processes are the main determinant of moral judgment has been criticized (Haidt 2001). In fact, there are two theoretical perspectives on the study of cognitive processes of moral judgment. The first is the Kantian theory, which Kohlberg adopted, which assumes that rational processes are more active than affective processes when making a moral judgment. In this theoretical approach, although emotional forces are – at least in part – involved, the main determinant of moral judgment is essentially rational. So Kohlberg thinks that the goal of a layperson in making a moral judgment is to reach the normatively superior moral principle like a truth-seeking scientist who always tries to find the universal principles of nature. According to this approach, someone with sufficient cognitive reasoning ability is more likely to score on higher levels of morality. The second theoretical approach to the psychological origins of moral judgment is the Humean sentimentalist approach (Haidt 2001). According to this approach, we use our intuitive rather than our rational processes when making a moral judgment. Accordingly, when an event occurs, strong emotions such as disgust or anger emerge that lead us to intuitively conclude that the

situation is morally right or wrong. After the moral judgment, we use our rational processes only for justification of the previous, already made moral judgment. To test this sentimentalist approach of Hume, the Julie and Mark scenario, which is well known in the literature, is used. In this scenario, the participants read the following scenario:

Julie and Mark are brother and sister. They are traveling together in France on summer vacation from college. One night they are staying alone in a cabin near the beach. They decide that it would be interesting and fun if they tried making love. At the very least, it would be a new experience for each of them. Julie was already taking birth control pills, but Mark uses a condom too, just to be safe. They both enjoy making love, but they decide never to do it again. They keep that night as a special secret, which makes them feel even closer to each other. What do you think about that? Was it ok for them to make love?

Although this scenario is defined as a harmless taboo violation (i.e., there is no direct harm behavior in this scenario; but see Royzman et al. 2015 for a counterargument), the majority of respondents automatically describe the incest behavior in the scenario (in which the feeling of disgust is activated) is morally wrong, and, in doing so, they use their intuitive and low-effort thinking styles (Haidt 2001). Only when they are asked why, do they seek to justify their judgment by using their analytic (high-effortful) thinking processes. Overall, Hume's alternative (sentimentalist) theoretical framework, therefore, claims that we, as a lawyer, try to justify our moral decisions rather than to seek the truth, as do scientists when making moral judgments. This is a direct critique of Kohlberg's rationalist view of moral judgment.

Another theoretical criticism is that the moral judgments scored as conventional level always correspond to traditional and conservative values, whereas those judgments scored as post-conventional level are mostly related to liberal values of justice and universalism. Haidt (2012) argues that this hierarchical approach is a natural result of the age of Enlightenment and thus is biased toward Western thinking style. However, according to Haidt and Kesebir (2010), this hierarchical approach suggested by Kohlberg is

simply wrong, because almost every moral principle that Kohlberg proposed has an evolutionary background and is present in every human being. However, the conservative moral values, scored as conventional level, are suppressed by political liberals (and the majority of Western people) by spending cognitive effort, and as a result, they perceive those foundations as morally irrelevant. However, when we look at the rest of the world (i.e., non-WEIRD cultures: Western, educated, industrialized, rich, and democratic cultures; Henrich et al. 2010), those who value universal principles of justice and fairness (i.e., post-conventional morality) constitute only a small minority (see also Shweder et al. 1997). Hence, the theory's view of liberal values as the top and hierarchically superior level of morality is substantially criticized, and it is thought that Kohlberg's theory of moral development is developed in a way that has a direct Western cultural bias. Apart from that, this hierarchical structure is criticized on its own. Rest (1979), for example, claims that some participants were moving backward in stages. However, since Kohlberg considers the development of cognitive development as related to moral development, he claims that the more the cognitive development increases, the greater the moral development.

Another criticism is related to alleged gender bias embedded in Kohlberg's theory of moral development. In the studies of Kohlberg, men generally score higher than women. However, Gilligan (1977) attributed this to the fact that the theory is constantly tested on male samples and that the higher levels are formed by principles such as justice that men value more. In fact, women often focus more on harm principles than on justice, but justice is considered as a higher moral principle in Kohlberg's classification.

In addition to this male-female discussion in terms of Kohlberg's theory of moral development, this can be seen as a methodological limitation as well since Kohlberg often conducted research with male participants. More importantly, however, Kohlberg sought to observe age-related changes using cross-sectional designs. In other words, one-to-one interviews with children of different ages were conducted to understand what

kind of differences there were between different ages instead of conducting longitudinal studies with the same participants. Although later Colby et al. (1983) conducted a 27-year longitudinal study showing that Kohlberg's theoretical approach is supported, there is still some controversy today regarding the validity of the methods used by Kohlberg.

In addition, some limitations of the method he used were later reported. For example, the moral dilemmas that are used are very artificial, which in turn might lead to a serious problem for ecological validity. Rosen (1980) reports that many of the dilemmas used by Kohlberg are very artificial. For example, the Heinz dilemma is very artificial for the children in the sense that the majority of the participants of Kohlberg range between 10 and 17 years of age, who have not been married and have never had a similar dilemma in their lives before. A second limitation of the scenarios used is the use of completely hypothetical scenarios. However, it is known that there can be discrepancies between hypothetical decision-making and real-life behavior, and the participants can sometimes report on the hypothetical scenarios that they will do things that people will not do in real life (Bostyn et al. 2018).

Conclusion

Kohlberg's theory of moral development can be considered as one of the first systematic – and empirically testable – theoretical approaches trying to understand the developmental stages of moral judgment, which is based on Piaget's moral theory. However, as outlined above, this approach is subject to substantial criticism from both the theoretical and the methodological perspectives and gives way to alternative theoretical approaches such as the moral foundations theory (Haidt 2012) and morality as cooperation theory (Curry et al. 2019). However, it is important to note that it maintains its claim to be the richest theoretical approach to date to explain especially how morality develops, which is lacking in the contemporary alternative theoretical approaches. In this respect, alternative theoretical approaches

that emphasize the developmental sequences of moral judgment are needed in the field of moral development.

Theory of Senescence

Bryan L. Koenig
Department of Psychology, Washington
University in St. Louis, St. Louis, MO, USA

Synonyms

[Aging](#)

Definition

The explanation of degradation to the body due to accumulated physiological defects that make an

individual increasingly susceptible to death at older ages as having evolved because natural selection is stronger earlier in life than later, resulting in (a) selection favoring genes that are beneficial during youth even if harmful later in life and (b) the accumulation of mutations that are expressed only at ages after which natural selection is too weak to remove them.

Introduction

Salmon breed once, after which they immediately die (Haldane 1941). Human women cease ovulating (and therefore reproducing) sometimes around 40 years of age but often live to twice that long (Hrды 2011). Some deep-water rockfish have lifespans longer than 200 years (Cailliet et al. 2001). These examples illustrate how diverse aging processes can be across species. Given that natural selection favors genes that enhance fitness, not those that reduce it, “The problem raised by senescence for evolutionists has been to devise a credible theory of this apparently deleterious phenomenon by natural selection” (Charlesworth 1980, p. 214). In 1952, the title of Medawar’s impactful article on aging was *An Unsolved Problem of Biology*. Holliday (2006), published an article titled *Aging is No Longer an Unsolved Problem in Biology* (see also Hayflick 2007). As these titles suggest, scientists now better understand how natural selection results in organisms that age, but some mysteries remain.

Meaning of the Term Senescence

Medawar (1952) distinguished between *aging*, by which he meant getting older in the sense of passage of time, and *senescence*, which he defined as the “change of the bodily faculties and sensibilities and energies which accompanies ageing, and which renders the individual progressively more likely to die from accidental causes of random incidence” (p. 12). Note that by this definition, age-related genetic diseases such as Huntington’s disease would be considered part of senescence, whereas pathogenic diseases such

as AIDS would be the “accidental causes” mentioned by Medawar. Some researchers have also included age-related reduction in fecundity as being part of senescence (Rose and Charlesworth 1980). Rose and colleagues (2012) provided another suggestion that fits well with the perspective of evolutionary psychologists when they defined aging as “neither more nor less than the deterioration of adaptation with adult age” (p. 3).

Reduced Selection Pressure with Increasing Age

Accepted theories of aging build on the insight of Ronald A. Fisher first proposed in 1930 that natural selection should be weaker on organisms as they become older. He based this conclusion on his idea of *reproductive value*: the number of offspring an organism of a specific age is expected to contribute to the next generation summing across the current age to the end of the expected lifespan. By this definition, reproductive value must decrease with age. Older individuals contribute fewer offspring during the remainder of their life, on average, than younger individuals to the next generation; therefore, selection acts with less force with increasing age.

Fisher did not relate the weakening of selection with age to the evolution of aging. This was done first, albeit superficially, by John B. S. Haldane in 1941. Peter B. Medawar, who received a Nobel Prize for unrelated work on organ transplants, provided the first thought-out argument on the matter in 1952. He built an argument that the strength of natural selection should vary across ages using a metaphorical population of potentially immortal test tubes. They are immortal in that they do not deteriorate with age (they are nonsenescent) but they may be killed (broken) by dangers in the environment. If the rate of death due to these dangers is constant across age, as is birth rate, then an age-structured population will result that consists of more young individuals and fewer elders. This is because as individuals get older their cohort will be smaller due to a larger proportion of their fellows having been killed. From this it is clear that even in a population without senescence, relatively fewer

older individuals are expected. Next, note that even though the rate of reproduction is the same for individuals of all ages, younger individuals will contribute more offspring to the next generation merely because there are more of them. Next, Medawar asks the reader to consider if sometimes individuals spontaneously died. Such a death would be a near complete loss of offspring production for young individuals but have little effect on how many offspring older individuals have. We can now see that a gene that caused spontaneous death would be much worse for the lifetime reproduction of younger than older individuals, and therefore that selection should be stronger for genes expressed in the young and weaker for genes whose expression does not happen until late life. In this scenario, selection would drive harmful genes to be expressed later in life (to the extent possible, see also Haldane 1941) until they are expressed at such a late age that so few animals lived sufficiently long for selection to matter.

William D. Hamilton (1966) showed that Fisher's reproductive value was not quite the right mathematical foundation for the evolution of aging. Hamilton's modified analysis identified two complementary *scaling factors* that are alternatives to reproductive value as ways of understanding how the strength of selection differs across age. The *survival factor* estimates how much selection can act on longevity for members of different age groups based on how much individuals in the age groups will contribute to the next generation. The *fecundity factor* estimates how much natural selection can work on the fecundity of different age groups. For Hamilton's factors but not reproductive value, in stable or increasing populations, the strength of selection is greater on younger than older age groups, but for shrinking populations with fewer younger individuals the strength of selection shifts to be stronger on older age groups. A notable feature of these forces is that with sufficient age they reduce to zero, meaning that selection no longer works on mortality or fecundity. Survival or fecundity rates need not themselves be zero, however, so Hamilton's scaling factors predict that aging should stop at sufficiently advanced age (Rose

et al. 2007). This counterintuitive finding has been demonstrated in evolution experiments using flies (Curtsinger et al. 1992) and in demographic data of humans (Vaupel et al. 1988).

Theories of the Evolution of Aging

Ultimate explanations of aging – how it evolved – differ from proximate explanations – how it occurs in the physiology of individuals during the lifespan. Numerous proximate mechanisms have been proposed, including wear and tear, toxin and metabolite build up, planned cell death, somatic DNA damage, free radicals, telomere depletion, and so on (Eisenberg 2012; Warner et al. 1987). Such proximate explanations, however, do not indicate why aging evolved. Moreover, ultimate mechanisms are relevant for species with specialized germ cells (reproductive cells) but not for species that reproduce by cellular fission such as protozoa which can be considered to live indefinitely (Bell 1984). Proximal theories make no such distinctions regarding germ line. Bell (1984) showed that this distinction is important and that evolutionary theories provide value beyond proximal explanations by demonstrating that age correlates with survival rates for invertebrates that reproduce via eggs but not those that reproduce by dividing their body. Comfort (1956) argued that aging is unrelated to evolution because wild animals rarely become elderly, but even in humans the effects of aging can be seen when people are in their thirties (Williams 1957).

Weisman (1891, as cited in Williams 1957) proposed the first theory of the evolution of aging. He argued on the one hand that aging was the same as the breakdown that occurs during mechanical wear and tear and on the other that a death mechanism evolved to remove the costs imposed by the elderly on the group. However, as Medawar (1952) points out, this logic is circular because it first assumes older individuals have aged then explains that aging evolved to remove those burdensome elders. Williams (1957) criticized the theory by arguing that cells are dynamic systems that can repair and replace themselves and so the analogy between aging and wear and

tear was weak at best. Regarding the death mechanism, Williams noted that not only has no death mechanism ever been found but also that Weisman's theory relies on population-level selection and so requires many assumptions that are complicated and therefore far from parsimonious (unlike his own proposal discussed below that relies on individual-level selection).

Haldane (1941) suggested that since selection cannot work after the end of reproduction (due for example to death), ages older than occur in nature have such reduced strength of selection that populations would build up harmful mutations that would be expressed at unnaturally advanced ages. Haldane mentioned this idea briefly, but Medawar (1952) developed it much more substantially. This theory is referred to as the *non-exposure to selection theory* (Nesse 1988) or *mutation accumulation theory* (Carnes et al. 2008). It argues that harmful mutations in germ lines (DNA that is passed to offspring) will not be eliminated by natural selection if they would be expressed only in relatively old individuals that live beyond the species lifespan in the wild. By this theory, when organisms are cared for and protected by their environment (like zoo animals or modern humans), they live unnaturally long lives and therefore express genes that cause aging that is unseen in wild animals. In short, this reduced or absent selection pressure at later ages allows harmful mutations to accumulate in a population. Haldane (1941) suggested that selection would favor modifier genes that postpone to a later age the expression of harmful mutations. Charlesworth (1980), however, argued that such modification seems unlikely given that the expression of mutations expressed late in life is rare and so the force of selection on their modifiers would be weaker than random sampling of genes or their harm might be offset by any beneficial pleiotropic effects.

Nonexposure to selection theory is widely acknowledged as accurate, but another theory is also considered accurate and to explain more aging in the world. It was also mentioned by Medawar in 1952. He suggested that selection would favor genes with beneficial effects early in life even if they had harmful effects later in life

because selection is stronger on younger than older individuals. This explanation, commonly referred to as *antagonistic pleiotropy*, was mentioned by Medawar only in passing but substantially developed not long after by George C. Williams (1957) in the very influential paper, *Pleiotropy, Natural Selection, and the Evolution of Senescence*. This paper, along with that of Medawar, inspired much of the research on senescence that would follow. Williams argued that selection would strongly favor genes whose effects increase the likelihood of survival or reproduction for a large part of an organism's lifetime reproductive capability – even if those same genes were harmful later in life. For example, a genetic effect that facilitated survival during birth has an impact on the whole of an organism's possible reproductive potential and so would undergo strong selection. By contrast, selection would be weaker for harmful genetic effects that arise later in life because they reduce the organism's likelihood of survival or reproduction for the relatively small fraction of the organism's total reproductive potential. The size of the effect of genes on fitness matters as well, but Williams's theory holds if some genetic effects will benefit organisms sufficiently in early life that they are maintained in the population despite fitness costs later in life. And it is these fitness costs later in life that correspond to the degradation of the body that we refer to as senescence.

William D. Hamilton (1966) did a mathematical analysis of factors related to mortality rates and concluded that his analyses were consistent with the arguments of Williams (1957). He also noted that most age-dependent effects are likely to be the onset of effects that continue rather than effects which are active and then deactivated later. He concluded from this analysis that “senescence is an inevitable outcome of evolution” (p. 12) and would be expected even in a population of initially immortal (nonaging) individuals. Those who reproduce earlier would produce a greater proportion of the offspring in the next generation, and so selection would favor earlier reproduction, with a result being that later-life harmful pleiotropic effects would occur (and produce aging).

Brian Charlesworth (1980) noted an additional way that the reduction in the strength of selection with increasing age could influence senescence. In a nonaging population (mortality rates are identical across ages), natural selection would more strongly favor genetic mutations that increase survival likelihood earlier in reproductive life as compared to later in life. This would result in mortality rates being lower earlier in life than later in life – even if the genes did not have harmful pleiotropic effects later in life. By this approach senescence would reflect youthful vigor rather than aged decline.

Thomas B. L. Kirkwood (e.g., Kirkwood and Rose 1991) addressed senescence in a manner complementary to the population genetics approach of Medawar (1952), Williams (1957), and Hamilton (1966). Kirkwood's approach – *disposable soma theory* – considers how an organism should optimally invest resources in body maintenance versus development or reproduction. The theory can be understood by considering various levels of investment in maintenance. At one extreme, the organism invests nothing in bodily maintenance, in which case its body would quickly die from the accumulation of unrepaired defects and bodily damage. The organism therefore should invest some in bodily maintenance. On the other end of the spectrum, an organism that invested exclusively in bodily maintenance might be able to repair all somatic damage and live agelessly. However, such an organism would increase its fitness if it instead invested slightly less in bodily maintenance and instead invested in growth or reproduction. Given this, organisms should invest some resources outside bodily maintenance. Considering organisms which invest less and less in bodily maintenance, a boundary arises where an organism would suffer from senescence if it invested any less in somatic maintenance. Disposable soma theory predicts that such an organism would be better off if it invested less in bodily maintenance than required to enable immortality. This is because such an organism will eventually die from environmental dangers anyways, and so some of the somatic investment would be wasted – and it could instead have been better invested in reproduction or

growth. The certainty of eventual death pushes the optimal amount of investment in somatic repair below that required for indefinite survival, freeing those resources for better use when the organism is more likely to be alive – that is, when it is younger. The common element in this theory and antagonistic pleiotropy is that, in effect, natural selection trades late survival for enhanced early fecundity.

The Apparent Anomaly of Human Post-reproductive Survivorship

Both Williams (1957) and Hamilton (1966) noted that humans outlive basic theoretical predictions that senescence should result in death once an individual can no longer reproduce, as occurs dramatically in salmon (Haldane 1941). Williams and Hamilton explained the extended survivorship as likely resulting from assistance provided by parents and grandparents – an idea now referred to as the *grandmother hypothesis* (Hawkes et al. 1998). Another explanation is that humans invested in *embodied capital* by spending substantial time during an extended adolescence to master how to hunt and gather successfully in the local ecology, an early life investment that pays later in life (Kaplan et al. 2000). Hill and colleagues (Hill et al. 2007) suggest that grandmothing and extended niche-specialization have as a prerequisite an extended adult survivorship, which they suggest is due to human-reduced extrinsic mortality resulting from “food sharing and care of sick and injured individuals” (p. 453). This is consistent with the suggestion of Rose and colleagues (2007) that the evolution of human intelligence allowed us to avoid some early life sources of mortality and thus live longer, resulting in selection for a longer life span, which in turn increased the strength of selection at later ages – thus resulting in a positive feedback loop. This process is unlikely to have occurred in other species and is analogous to humans artificially selecting themselves for longer lives like scientist Michael Rose has done with flies. The evolution of human senescence is still an active area of investigation without a clear consensus.

Evidence

A review of genetics related to aging indicated that numerous genes have been identified that influence lifespan (Moskalev et al. 2014). A common feature of these genes is that they are involved in response to stress. For example, some “genes promote growth and reproduction while suppressing stress resistance” (p. 1071), a trade-off predicted by antagonistic pleiotropy theory. Other genes are responsive to ecological factors including crowding, food availability, temperature, light, and radiation. Still others are involved in dealing with toxins, immunity, basic cellular function, metabolism, and so on. Many of the types of factors for which these genes have evolved thus fit within expectations of antagonistic pleiotropy theory of aging because they are important for survivorship, especially early in life.

In a review of the biological literature, Brian Charlesworth (1980) found support for aging-related effects consistent with weaker selection with advancing ages (Hamilton 1966). First, aging is found in species that separate soma and germ cells but not for example in plants that reproduce vegetatively (Bell 1984). Second, species with greater external mortality tend to age faster. Third, species in which fecundity increases with age, such as in reptiles, sometimes have longer lifespans. Fourth, senescence starts immediately following reproductive maturity. However, survivorship should reduce quickly after reproduction ends due to mutation accumulation, but human females live after menopause. As mentioned above, various explanations have been proposed for this anomaly, such as the grandmother hypothesis. Nesse (1988) compared survivorship across ages with expected survivorship without senescence (i.e., using a constant mortality rate) for various species, and a substantial number of species showed clear evidence of senescence related to antagonistic pleiotropy but none provided clear evidence for mutation accumulation.

Perhaps the strongest evidence in support for the antagonistic pleiotropy theory of aging comes from experimental research with flies by Michael R. Rose and Brian Charlesworth. As reviewed by Kirkwood and Rose (1991), in selection

experiments, one population of *Drosophila* flies were allowed to reproduce without manipulation, whereas in another population the only eggs allowed to be fertilized were those produced late in the lifespan, which notably progressed to older ages over generations. Such experiments showed that experimental selection can indeed extend lifespan, in one case by 29 % over 15 generations, and females in that group reduced the number of eggs laid early in life and increased the number laid in later life. The population selected for old age showed decreased egg production early in life but increased resistance to various stressors, such as starvation, drying out, and environmental alcohol. They could also fly further. Kirkwood and Rose interpret these findings as supporting antagonistic pleiotropy because the health benefits are offset by reduced fecundity early in life.

Conclusion

Theories of the evolution of aging are based on the idea that the strength of selection weakens with increasing age. One theory of the evolution of aging is that mutations that are expressed only at unnaturally old ages would build up in a population and cause aging for individuals living in safer environments. A more prominent theory is that genes that have beneficial effects early in life but harmful effects later in life will be favored by selection and so become common. The later theory has garnished substantial support. In short, natural selection favors investments in the body and reproduction early in life at the cost of later-life survival because organisms are less likely to be alive at later ages.

Biofield therapies

Definition

An alternative therapeutic intervention, which purports to manipulate the energy field of the client through a non-touch technique for relieving the distress.

Introduction

Therapeutic touch is a therapeutic procedure that has been in use for the past few decades. It is a therapy from the alternative system of medicine (O'Mathúna 2016). This technique was developed by Dolores Krieger and Dora Kunz (Straneva 2000). During the “therapeutic touch” procedure, the therapist move his/her hand over the body of the patient to manipulate the energy field and restore the balance of the surface energy field (O'Mathúna 2016). The word “therapeutic touch” is a misnomer, as, during the procedure, there is no actual skin to skin (body to body) contact between the therapist and the client; however, there occurs contact between energy fields of the therapist and client. It is also known as an energy-based treatment modality. It has been considered as an important intervention modality intended to provide holistic care in nursing practice (Hanley et al. 2017). Therapeutic touch is often used for facilitating subjective well-being, comfort, and relaxation to patients with various illnesses (Engebretson and Wardell 2007; Meehan 1998). It has been recognized as a complementary therapy by the National Center for Complementary and Alternative Medicine.

Basis of Therapeutic Touch

Existing evidence explaining the mechanism of action of “therapeutic touch” is not well understood by the current scientific knowledge. Explanations and claims regarding “therapeutic touch” by the therapists and clients still remain controversial due to its nonscientific nature (Meehan 1998). The theoretical explanations about therapeutic touch center around manipulation of energy field of the body of the client by the therapist (Umphred 2013). As per the existing explanatory models, the human body has an open energy field, which remains balanced in state in a healthy individual due to equal distribution in a biological symmetrical body. From this perspective, any imbalance in the body's energy field results in development of illness/disease (Umphred 2013). The ancient Indian as well as Chinese system of medicine emphasizes the existence of a body energy system and its relevance in maintaining the healthy body and mind. On this basis, therapeutic touch technique was founded and gained its popularity.

Clinical Use of “Therapeutic Touch”

The therapeutic touch technique has been used in treatment of various physical illnesses, ranging from wound care to pain, cardiovascular diseases, cancer treatment, as well as terminal illnesses (Monroe 2009; O'Mathúna 2016; Snyder 1997; Tabatabaee et al. 2016; Umphred 2013). In pain management, therapeutic touch was found to be effective, and as there are no risks associated with it, it may be considered as a useful therapeutic intervention in pain management (Monroe 2009). This therapy has been found effective for symptom relief and is hypothesized to work upon the immune system and improve the immune functioning although it is important to note that the evidence for such an effect is not very concrete (Jain et al. 2015).

Similarly, therapeutic touch has been studied in patients with anxiety disorder. A Cochrane database review revealed that the existing evidence in support of therapeutic touch is not sufficient and emphasized that extensive research with sound

methodology is necessary to provide evidence of its efficacy (Robinson et al. 2007). Nevertheless, some evidence suggests that therapeutic touch has been effective in alleviating the mood symptoms and emotional problems among otherwise healthy women with respect to objective standardized inventories and biomarkers (Lafreniere et al. 1999).

Process of Therapeutic Touch

The process of “therapeutic touch” is a soft, non-invasive general and sophisticated approach. It is individualized to meet the needs of the healing partner (client in need of healing). The process of how the therapeutic touch intervention is purported to occur is by transferring of the energies (field of energies that normally surround bodies of living organisms) (Fig. 1). The therapist, who is trained and certified to perform the therapeutic touch, performs this therapy. They attempt to alter the paradigm of their consciousness to enable their hands to pattern the energies of the sick or painful body part. The procedure requires the healer to stand or sit and the client to lie down or sit in relaxed state. The therapist first assesses the energy patterns by moving his/her hands over the receiver from 2 to 6 inches away from the body. Then, the therapist makes hand movements for correcting the imbalance in energy fields so that the energy can flow freely and heal the person internally (Umphred 2013). During the process, the therapist (healer) sweeps the energy over the

body from the area where it is congested. This particular activity is known as “unruffling the energy field” (Umphred 2013). These therapies usually last 20 to 30 minutes followed by a period of rest. By therapeutic touch procedure, the therapist creates a conducive environment which facilitates the process of healing.

Phases of Touch Therapy

The procedure of touch therapy encompasses of the following phases:

- 1. Centring
- 2. Assessing
- 3. Intervention balancing and rebalancing
- 4. Evaluation and closure

Centring: To bring one’s energy awareness by meditation, guided breathing, imagery, and changing their energy fields to bring a conscious change.

Assessing: Here the therapist assesses the changes in the pattern of the energies by moving his/her hands in 2–6 inches above the body from the head to feet following a rhythm and symmetrical manner. Therapists have reported the feeling of warmth, tingling, and presence of blockade, pulling, and coolness during assessment of clients, which purportedly indicates that deviations in the energy systems are present.

Intervention balancing and rebalancing: In this phase the therapist balances the energy fields

Therapeutic Touch,
Fig. 1 Depiction of a
typical “touch therapy”
session

as per assessment and balances the excess energies and restores lost energy. They make sweeping movements over the areas affected.

Evaluation/closure: The therapist intuitively decides (using their professional expertise) when to terminate the session. The ongoing assessment of the energy fields and continuous feedback from the individuals determine the end of the therapy (Koopsen and Young 2009).

Conclusion

Therapeutic touch is one of the important interventions practiced by nurses as a part of the holistic therapies. It considers individuals as a whole and as having potent ability to heal oneself. Although there is lack of strong scientific evidence on the mechanism of action of the therapy, it has shown promising results in managing pain and promoting healing. There is need of extensive research to understand the basis of this therapy.

Introduction

The theory of evolution by natural selection is the unifying paradigm of biology and indeed of all the life sciences – it explains and integrates a huge diversity of known findings and predicts an astonishing number of new ones (Alcock 2009; Coyne 2009). It has been famously suggested that nothing in biology makes sense except in the light of evolution (Dobzhansky 1973). Prominent philosopher Daniel Dennett has said “If I were to give an award for the single best idea anyone ever had, I’d give it to Darwin, ahead of even Newton and Einstein and everyone else” (Dennett 1996, p. 21). Indeed, scientists, historians of science, and philosophers of science generally regard evolutionary theory as one of the most predictively powerful and explanatorily successful theories in the history of science (Alcock 2009; Coyne 2009; Dawkins 2009; Dennett 1996).

And yet, despite the simplicity of the core idea and its universal acceptance in the scientific community (e.g., Pew Research Center 2015), misunderstandings regarding natural selection abound. Such misconceptions even appear in college textbooks and among students who have taken college-level evolutionary biology courses (Alters and Nelson 2002; Gregory 2009; Nehm and Reilly 2007; Nehm et al. 2008; Winegard et al. 2014). A review of ten textbooks in social psychology revealed at least one factual error

about inclusive fitness theory in *each*, and typically two to three (Park 2007). In this entry, we briefly identify and dispel 13 of the most pervasive misunderstandings of evolutionary theory.

Misunderstanding 1: Natural Selection Is a Random, Chance-Driven Process

Probably the most pervasive misunderstanding about natural selection is that it is a chance process.

In simplified form, evolution takes place in two steps: mutation and natural selection (in reality, the process is more complicated than this). In the first step, random genetic mutations arise. These mutations may turn out to be beneficial, detrimental, or neutral. This step is random, involves no foresight, and does not take into account what the organism “needs” or would benefit from. Indeed, more mutations turn out to be detrimental than beneficial. In the second step, mutations with harmful effects on reproduction are filtered out by natural selection, which acts like a sieve (Dawkins 1982). By contrast, those that have beneficial effects on reproduction are more likely to be passed on and increase in frequency over time.

This second step is quintessentially *non-random*: some mutations make it past natural selection’s filter precisely because they are beneficial, and others fail to make it past the filter precisely because they are harmful. This is the opposite of randomness: it is an orderly and predictable process in which there is a logical connection between the effect a mutation has and its likelihood of making it past the filter of natural selection. By contrast, a random process would be unpredictable and would have no systematic connection between the effects of a mutation and its likelihood of making it into the next generation.

The problem seems to be that people sometimes confuse mutation (which is random) with natural selection (which is not random). To make matters worse, they may conflate one or both of these processes with evolution, which is the *outcome* of these processes (see Misunderstanding #11 for more detail on the distinction between evolution and natural selection).

To avoid these errors, it helps to remember that natural selection is the *nonrandom sorting of randomly mutated genes*. Finally, because natural selection is not random, the process it drives – evolution – is also not random.

The misunderstanding that natural selection is a chance process is particularly pernicious because of its downstream effects. It is nearly impossible that a random, chance-driven process could explain the complexity, utility, and apparent purposiveness of the adaptations we see in the biological world. As a result, falling into the erroneous belief that natural selection is a random process might lead some people to reject evolution altogether on the basis of a conceptual mistake.

Misunderstanding 2: Natural Selection Is Primarily About Survival

It is common to think of natural selection as being primarily about survival, but in truth, it is primarily about reproduction. *Differential reproductive success* – not survival – is the driving engine and the “bottom line” of evolution. It is possible to illustrate this point using both logic and empirical evidence.

To illustrate the point logically, imagine two genes, each of which has two distinct effects (these are called “pleiotropic effects”). Gene A leads the animal in which it resides to live to be 100 years old, but makes it infertile. Gene B leads the animal in which it resides to die at 25 years old, but after having had several offspring. Which gene will have greater representation in the next generation? The answer is that gene B will be well represented, whereas gene A will be entirely absent. This thought experiment helps to demonstrate that when the two conflict, reproduction trumps survival.

It is also possible to illustrate empirically that when survival and reproduction conflict, survival takes the backseat. Examples abound. The peacock’s tail is a massive burden to survival but is crucial in seducing peahens (Darwin 1871; Cronin 1993). Human testosterone is a powerful immunosuppressant but human females are attracted to

testosterone-dependent traits such as a strong jawline and a high shoulder-to-hip ratio (Buss 2015; Al-Shawaf & Lewis 2018). Male redback spiders willingly offer themselves to their mates for cannibalization – they die, but in doing so, they double their paternity relative to noncannibalized males (Andrade 1996, 2003).

In other words, when it comes to evolution, reproduction is more important than survival. Many species take this to an extreme, living only long enough to reproduce and then dying immediately thereafter. This is so common in nature that the phenomenon has a recognized name – *semelparity* – and examples of species that do it range from desert agave plants to butterflies to bamboo plants to Pacific salmon (Quammen 1985). Perhaps even more morbid are those species that successfully reproduce – only to be promptly devoured by their offspring. The matricidal gall midge *Miastor* does this, producing larvae that eat it alive from the inside out (Quammen 1985). The key point is that in evolution, survival is important only insofar as it eventually leads to reproduction. Both logical thought experiments and an abundance of empirical examples illustrate that when survival and reproduction conflict, it is invariably reproduction that wins (Alcock 2009; Dawkins 1976; Hamilton 1964; Williams 1966).

Misunderstanding 3: “Natural Selection” Refers to an Agent That Actively “Selects” the Best Organisms for the Next Generation

“Natural selection” is an unfortunate misnomer. It gives the impression that some kind of causal agent is actively “selecting” traits for inclusion in the next generation. Nothing could be further from the truth: there is no agent and there is no selection. Stated differently, there is no guiding hand in the process of natural selection – the process is blind, mechanistic, and passive.

“Differential reproductive success by virtue of heritable differences in design” is a much more accurate description of the process: some organisms reproduce more than others, and this simple

fact is the key driver of evolution by natural selection. But because “differential reproductive success” is a mouthful, scientists and laypeople alike often use “natural selection” as shorthand. That is perfectly fine as far as it goes, but it is helpful to remember that this is just shorthand for a longer and more cumbersome phrase.

In sum, “differential reproductive success” is a little wordy, but it is more accurate in that it (a) describes what is actually occurring, (b) does not suggest the presence of a hidden causal agent, and (c) does not misleadingly imply some form of active selection. It may therefore be beneficial for readers and writers to bear in mind that “natural selection” is a linguistic shorthand rather than a descriptively accurate term for the process that drives evolutionary change.

Misunderstanding 4: Natural Selection Is Teleological – It Is Working Toward a Goal or Final Purpose

Natural selection does not have a final goal or *telos*. It also has no foresight – in other words, it is impossible for natural selection to take into account future conditions. Though the products of selection can be beautiful and complex, the process itself is blind and mechanistic.

For example, if a certain species of mammal would benefit from evolving a slightly thicker coat of fur, this does not mean that natural selection will guide it toward that goal. First, a beneficial mutation must arise that contributes to said trait. This stage of the process is entirely random and is not affected by what the animal “needs” or would benefit from. In fact, harmful mutations are much more common than beneficial mutations (because there are many more ways to disrupt a functioning biological machine than to improve it). Second, if the new mutation happens to confer a survival or reproductive advantage, natural selection will favor it, and it will tend to increase in frequency as the generations pass. But it is impossible for natural selection to *anticipate future needs* and lead species toward a distant goal state, as natural selection cannot look ahead and does not have goals.

Nor does natural selection inevitably lead to “progress” in the sense of greater intelligence or greater complexity. A common misconception is to think of evolution as progressive – always improving or moving toward greater complexity. In reality, there is no predetermined direction to evolution. Natural selection can easily cause a species to lose complexity when the environment demands it (see e.g., Misunderstanding #6 and Al-Shawaf and Zreik 2017). For example, several species have slowly evolved to lose their sight after moving into pitch-black caves. Since sight is no longer useful in such an environment, natural selection led these species to lose their vision and channel the metabolic resources previously used for sight to other physiological needs such as immune function or cell repair.

Natural selection is a tinkerer, not an engineer (Jacob 1977). An engineer can look ahead to her final goal and implement changes that help her get closer to that final goal. She can also return to the drawing board any time she pleases to fix a mistake. By contrast, natural selection cannot look ahead, has no goal, and can only build adaptations based on the genetic variants already available in the population at the time. In short, natural selection has no *telos* or endgame.

Misunderstanding 5: Natural Selection Favors the Survival of The Species

One of the most common misconceptions about evolution is that natural selection favors the survival of the species. In reality, natural selection works primarily at the level of the gene and the individual bodies in which genes reside – not at the level of groups, subspecies, or species (Hamilton 1964; Williams 1966).

George Williams, one of the most important evolutionary biologists of the twentieth century, showed several decades ago that group selection is theoretically possible – but likely to be extremely rare in nature. For group selection to work, several preconditions must be in place – and these preconditions are themselves very rarely met in nature (Williams 1966). Recent years have witnessed a resurgence of interest in group

selection (e.g., Wilson and Sober 1994; Henrich 2004), but most evolutionary biologists and psychologists agree on the following: (1) group selection is theoretically possible, but (2) genic-level and individual-level selection are considerably stronger than group-level selection, (3) there is no clear empirical evidence that group selection applies to humans, and (4) group selectionist thinking does not appear to have led to any testable new hypotheses (Delton et al. 2011; Krasnow et al. 2012, 2015, 2016; Krasnow and Delton 2012; Pinker 2012). By contrast, orthodox genic-level and individual-level selectionist thinking have led to many hundreds of testable hypotheses, which have in turn led to thousands of empirical studies. This suggests that, unlike genic-level and individual-level thinking, group selectionist thinking may not be especially generative or fruitful as a scientific theory (Alcock 2017).

An important sidenote is worth mentioning: even if group selection turns out to be more widespread in nature than we previously thought, it would still not be the case that adaptations evolve for the good of the *species*. Even dyed-in-the-wool group selectionists are primarily focused on small, local groups – not whole species. It is therefore incorrect, for example, to think we have sex “to perpetuate the species”. We have sex because we are the descendants of ancestors whose sex led to reproduction, and so we inherited their tendency for sexual motivation. An incidental side effect of this is that the species as a whole may sometimes benefit. Outcomes that are beneficial to groups can indeed occur, but they are not the proper biological function of adaptations, they are incidental side effects.

Misunderstanding 6: Natural Selection Builds Perfectly Designed Biological Mechanisms

There are several constraints that limit natural selection’s ability to craft optimally designed mechanisms. These include (a) time lags, (b) historical constraints, (c) constraints due to available genetic variation, (d) unavoidable trade-offs, (e) imperfections at one level due to

selection at a different level, (f) mistakes due to environmental unpredictability, and (g) antagonistic pleiotropy (Al-Shawaf and Zreik 2017; Dawkins 1999). We highlight only three of these in this entry: time lags, historical constraints, and unavoidable trade-offs (for a more thorough discussion, see Al-Shawaf and Zreik 2017).

Time lags refer to the fact that natural selection is a slow and gradual process. Animals are adapted to *past* environments, not current environments (Dawkins 1999). If the environment changes rapidly, natural selection may be too slow to catch up. For example, human taste preferences for fat, sugar, and calorie-dense foods were adaptive when food was scarce during the evolution of our species. By contrast, in today’s world of cheap and ubiquitous fast food, these same taste preferences lead to obesity, type II diabetes, and cardiovascular diseases (Buss 2015). The environment has changed too quickly for the slow, cumulative process of evolution to catch up. Time lags have rendered our previously adaptive taste preferences maladaptive.

A second important constraint on natural selection comes from a species’ *evolutionary history*. Once a species has evolved a certain nervous system or body plan, this constrains what it is capable of evolving next. Given their current body plan, it would be difficult or impossible for elephants to now begin to evolve wings, say, or an exoskeleton. Once a species finds itself on a certain evolutionary trajectory, this limits where it can go next. In other words, the phylogenetic background of a species affects what it is capable of evolving next – history constrains evolution.

Unavoidable trade-offs impose a third constraint on natural selection. Gazelles under predation pressure from wolves may evolve longer legs, enabling them to run faster and increasing their likelihood of escape. But longer leg bones are more brittle and more likely to break. The gazelles therefore face an unavoidable trade-off: longer, more gracile bones with enhanced capacity to flee but increased likelihood of breaking, or shorter, more robust bones with a lower likelihood of escape. The key point is that every adaptation comes with a cost, and this leads to unavoidable trade-offs. Trade-offs, in turn, make it impossible to optimize every parameter simultaneously.

These constraints, along with several others, make it impossible for natural selection to build perfectly designed biological mechanisms (see Al-Shawaf and Zreik 2017; Dawkins 1999, for an extended treatment of the constraints on natural selection). It is because of these constraints on natural selection that we are left with suboptimal designs such as the vertebrate eye (which has a blind spot) and the human esophagus and trachea (whose inelegant setup poses a serious choking hazard). Natural selection can build complex and functional mechanisms. It can even build mechanisms so sophisticated and impressive that engineers are studying them in an attempt to replicate their structure and function in artificial systems (e.g., the luminescence of fireflies, the sonar of bats, and the adhesive abilities of geckos; Bhushan 2009; Kim et al. 2012; Murr 2015). Nonetheless, despite these impressive feats, the constraints on natural selection limit its ability to craft truly optimal biological mechanisms.

Misunderstanding 7: Evolution Implies Genetic Determinism

One of the most widespread misunderstandings is that *evolution implies genetic determinism*. That is, many are under the impression that naturally selected behaviors or psychological mechanisms are genetically determined – that the claim “X is a product of natural selection” is equivalent to the claim “X is genetically determined.” It is emphatically not.

First, evolution by natural selection is an environmentally driven process, and it would not exist at all without the environment. Adaptations (the products of natural selection) require environmental input at every stage of their emergence: (a) initial evolution, (b) ontogenetic development, and (c) immediate activation (Buss 1995). Stated differently, adaptations only evolve in the first place because of an environmental challenge, often referred to as an “adaptive problem” (Buss 1995; Tooby and Cosmides 1992). Subsequently, adaptations require environmental input for their proper development during an organism’s lifespan. And finally, adaptations require environmental

input for their immediate activation in the present. This means that the environment is crucial to every product of evolution at every stage of the evolutionary process.

The second problem with the idea that natural selection implies genetic determinism has to do with the fact that nothing is determined by genes or environment alone. Genes and environment, working together, jointly codetermine every aspect of an organism – from its ears to its personality. Neither genes nor environment is capable of doing this alone. After all, genes are like a recipe for making a body, and environmental input is like the raw ingredients. The ingredients alone are impotent, and the recipe alone is equally impotent (e.g., Dawkins 1976; Ridley 2003). As such, no credible scientist thinks the products of evolution are genetically determined, and the claim that a psychological mechanism is a product of natural selection is *not* in any way equivalent to the claim that it is genetically determined.

It might be worth adding here that the often-misunderstood concept of *heritability* (percentage of variance in a phenotypic trait due to genetics) does not refer to a single individual; it refers to how much of the *differences* between individuals are due to *differences* in their genes as opposed to *differences* in their environments. For example, if the personality trait of extraversion has a heritability of 60%, this does not mean that Bob’s extraversion is 60% due to his genes and 40% due to his environment. Instead, it means that 60% of the *differences* between individuals in their extraversion is due to differences in their genes, and 40% is due to differences in their environments. For a single organism, every single trait is jointly codetermined by genes and environment. This even includes traits with 0% heritability or 100% heritability – there is simply no other way to build an organism. Stated differently, we must distinguish between two levels of analysis: the individual level (in which we are concerned with individual organisms) and the population level (in which we are concerned with the differences between organisms). Partitioning an outcome like height, IQ, or extraversion into percent due to genes and percent due to environment is meaningful at the population level of analysis but

meaningless at the individual level of analysis. A quip by Donald Hebb illustrates this point well: when asked whether nature or nurture makes a greater contribution to personality, he replied, “Well, which contributes more to a rectangle’s area – its length or its width?” (Meaney 2001).

In sum, there are two key points about the relationship between evolution, genes, and environment. First, environmental input is essential to the emergence and activation of all evolved mechanisms. Second, genes and environment jointly codetermine everything from an organism’s morphology to its behavior. For both of these reasons, it is wrong to think that evolution bears any relationship to genetic determinism.

Misunderstanding 8: Adaptations Must Be Present at Birth (or Must Emerge Very Early in Life)

An odd but widespread assumption is that adaptations – the products of natural selection – must be present at birth or must emerge very early in life. Features not present early in life are automatically assumed to be “learned,” not the product of natural selection. One key problem with this line of reasoning is that it mistakenly pits learning and evolution against each other as if they are competing explanations, when in fact they are not (for an extended discussion of the compatibility between learning and evolution, see e.g., Al-Shawaf et al. 2018; Lewis et al. 2017; Symons 1979; Tinbergen 1963). The other key problem is that there is simply no basis for the arbitrary assumption that the products of natural selection must be present at birth.

Teeth and breasts illustrate what is wrong with this principle: they are both adaptations *par excellence*, but they are not present at birth. Instead, they emerge at the appropriate developmental stage of the organism’s life. Natural selection builds adaptations that emerge at the correct point in ontogenetic development, not adaptations that are necessarily present at the moment a baby is born. Teeth and breasts (and pubic hair and facial hair, etc.) emerge later, when they are

needed, during the appropriate life stage. The same goes for walking and bipedalism: newborn infants cannot walk, but nobody doubts that bipedalism is a biological adaptation. Similarly, nobody doubts that flight or vision are exquisite biological adaptations, despite the fact that many newly hatched bird offspring can do neither.

In sum, adaptations – the products of natural selection – can “come online” during the prenatal phase, shortly after birth, or much later in life. There is no theoretically principled reason to stipulate that they must be present at birth. That is not how natural selection works – it works to produce adaptations that come online during the developmental phase in which they are needed, not ones that are present at a particular arbitrarily selected moment.

Misunderstanding 9: The Products of Evolved Mechanisms Are Fixed and Unchangeable

A key misconception is that if a certain behavior is the output of a mechanism built by natural selection, it is fixed and unchangeable. For example, people worry that if there is evidence of an evolutionary basis for aggression, warfare, or sexual infidelity, this somehow means that these undesirable outcomes are inevitable.

In reality, evolved mechanisms are flexible and their outcomes are rarely fixed. All evolved mechanisms require environmental input. Often, changing the input is enough to change the output. For example, all humans have callus-producing mechanisms in their hands. These evolved physiological mechanisms are designed to produce calluses in response to repeated friction of the skin. But this does not mean that the outcome – calluses – is unavoidable: simply remove the friction by wearing gloves, and these mechanisms will no longer produce calluses. By modifying the input, you have successfully changed the output (Buss 2015).

Behaviors produced by natural selection are no more fixed or set in stone than calluses. Indeed, evolved psychological mechanisms are exquisitely context-dependent and environmentally

sensitive (see Al-Shawaf et al. 2018, for an extended treatment of the centrality of context in evolutionary psychology). Even if socially undesirable behaviors such as aggression, warfare, or romantic infidelity have an evolutionary basis, this does not mean that we are stuck with them forever. Indeed, a wealth of evidence shows that war, violence, and other forms of aggression have been steadily declining throughout human history (Pinker 2011). In fact, our best chance of changing or eliminating socially undesirable behaviors will come from understanding them more deeply. Only when we understand the inputs, evolved decision rules, and outputs involved in an undesirable outcome will we have the information necessary to try to change it.

Misunderstanding 10: You Can Use the Principles of Natural Selection to Bypass the Psychological Level of Analysis and Predict Behavior Directly

It is common to think – especially among evolutionists who do not have a background in psychology – that there is nothing wrong with going directly from the principles of natural selection to predictions about behavior, skipping the psychological or information-processing level of analysis. But skipping the level of psychological adaptations – the information-processing machinery built by natural selection – can lead one astray (Cosmides and Tooby 1987).

Consider incest aversion. Studies suggest that the mind uses a few key cues during childhood to tag individuals as siblings, marking them as unsuitable sexual partners. Chief among these are childhood co-residence (years spent growing up with the other child in the same house) and maternal perinatal association (if you are the older sibling, observing your mother breastfeeding the other child). The human mind uses these two key informational inputs to tag someone as a sibling and consequently produces incest aversion at the thought of having sex with them. Normally, siblings encounter these cues during childhood and nonsiblings do not. But sometimes there is a mismatch – and these mismatches are revealing. For

instance, in the phenomenon of Taiwanese minor marriages, a young female child is betrothed to a young male child, and they are both raised by the boy's parents in the boy's parents' house. Because they grow up together in the same household (childhood co-residence), their brains mistakenly tag each other as siblings, producing incest aversion. As a consequence, the individuals involved in Taiwanese minor marriages report less sexual interest in one another, lower fertility rates, lower relationship satisfaction, and higher divorce rates (Lieberman et al. 2007; Lieberman and Symons 1998). In essence, the mind mistakenly coded a nonrelative as a sibling because it received the key informational input of childhood co-residence (Lieberman et al. 2003, 2007).

This process can fail in the opposite way, too: genetic siblings who do not receive the key informational inputs of childhood co-residence and maternal perinatal association may fail to psychologically tag each other as siblings, leaving open the possibility of being sexually attracted to each other later in life. This is exactly what happened to some siblings who were separated at birth, grew up apart, and later in life found each other and fell in love (Childs 1998). This outcome makes no sense unless you take into account the information-processing level of analysis. If you attempt to go directly from the principles of natural selection to behavior, the phenomenon appears incomprehensible – they are genetic siblings, so why are they sexually attracted to each other? By contrast, if you *do not* skip the information-processing level of analysis, the difficulty immediately disappears: these siblings were reared apart, so their minds did not receive the key informational inputs needed to produce incest aversion. That is why they are capable of being sexually attracted to one another.

In short, if you leapfrog the psychological level of analysis and attempt to go directly from the principles of natural selection to statements about behavior, you will make mistakes in both prediction and explanation (Cosmides and Tooby 1987). This brings to mind two quotes from foundational evolutionary thinkers, one by Donald Symons and the other by John Tooby and Leda Cosmides. To paraphrase Don Symons, the

evolutionist should focus on psychology and information processing. When he ignores these in favor of observable behavior, he is like the drunk looking for his key under the lamppost: he knows he dropped it in the dark, but under the lamppost the light is better (Symons 1979).

And as Tooby and Cosmides wrote so eloquently, “The fact that the brain processes information is not an accidental side effect of some metabolic process. The brain was designed by natural selection *to be* a computer. Therefore, if you want to describe its operation in a way that captures its evolved function, you need to think of it as composed of programs that process information” (Tooby and Cosmides 2005, pp. 16–17). In short, if you want to maximize the accuracy of your evolution-based predictions and explanations, you would do well not to skip the information-processing level of analysis.

Misunderstanding 11: Natural Selection Is the Only Driver of Evolutionary Change

Another important misconception is that natural selection is the only driver of evolutionary change. A variant of this misunderstanding is the erroneous belief that the terms “evolution” and “natural selection” are more or less interchangeable.

In reality, evolution is the *outcome*, and there are four evolutionary forces that drive it: mutation, genetic drift, gene flow, and natural selection (e.g., Futuyma and Kirkpatrick 2017). Mutation is a random heritable change in a gene or chromosome and constitutes part of the raw material on which natural selection works. Genetic drift is the random, chance-driven change in allele frequency from one generation to the next. Gene flow, sometimes called admixture or migration, is the movement of genes from one population to another. Natural selection, the fourth evolutionary force and the subject of this entry, is most accurately described as nonrandom differential reproductive success (see Misunderstandings #1 and #2).

To be clear, while natural selection is not the only driver of evolutionary change, it is a key one – and most scientists agree that it is the most

important one (Alcock 2009; Dawkins 1976; Dennett 1996; Williams 1966). It is also the *only* evolutionary force capable of fashioning adaptations or creating the appearance of design, the explication of which is the central explanatory task of evolutionary biology (Darwin 1859; Williams 1966).

This is an important point: while there are four different evolutionary forces, only one of them – natural selection – can create adaptations designed to solve environmental problems. The other three forces can cause evolution – defined as a change in allele frequencies in a population over time – but only natural selection can fashion complex specialized mechanisms like the porcupine’s quills, the turtle’s shell, or the angler fish’s bait, all exquisitely designed to solve key environmental problems in these animals’ lives.

In sum, natural selection is only one of four evolutionary forces, but it is the only one capable of fashioning adaptations.

Misunderstanding 12: Evolutionary Hypotheses Are Primarily Post-Hoc Storytelling – Also Known as “Just-So” Stories

One of the most widespread misunderstandings of evolutionary science – and of evolutionary psychology in particular – is that evolutionary hypotheses are post-hoc storytelling, also known as “just-so stories” (Gould and Lewontin 1979). Nothing could be further from the truth. There are two ways to appreciate why this is a mistake.

First, as in all sciences, evolutionary psychologists can proceed in two ways: using the top-down or bottom-up approach. In the top-down approach to science, researchers generate hypotheses and predictions directly from theory and subsequently go out and test their hypotheses. Since hypotheses and predictions in this approach are made *a priori* on the basis of theory, it is impossible for the top-down approach to be open to the charge of just-so storytelling.

By contrast, in the bottom-up approach, researchers first make an observation, and then generate a hypothesis to explain why that

observation might have occurred. This approach to science is *potentially* open to the charge of post-hoc storytelling, but only if the researcher *stops* after generating a hypothesis and fails to derive or test any new predictions from that hypothesis. Whether or not a proposed explanation counts as just-so storytelling depends entirely on this last step: if the researcher in question simply chooses to believe her hypothesis without generating and testing any novel predictions, then she is guilty of just-so storytelling. If, by contrast, the researcher uses the proposed hypothesis to generate novel, testable predictions, the charge falls flat. A cursory look at published evolutionary psychological papers makes it clear that most evolutionary psychological hypotheses are not open to this accusation, either because they used the top-down approach to generate *a priori* predictions (e.g., see Al-Shawaf 2016), or because they used the bottom-up approach but subsequently generated and tested novel predictions.

A concrete way of remedying the confusion here is simply to list examples where an evolutionary approach started from theory, generated novel hypotheses, and then used those hypotheses to derive new predictions which were subsequently tested in the lab and the field. There are literally hundreds of such examples, and many of them have been included in easy-to-read tables in previous journal articles. We therefore do not replicate them here but instead direct the reader to three articles where they can find plenty of such examples – as well as much more detailed discussions of why evolutionary hypotheses are eminently falsifiable. Key papers that include such tables and discussion are Buss et al. (1998), Ketelaar and Ellis (2000), and Lewis et al. (2017).

The underlying mistake seems to be thinking that if a discipline is partly *historical* in nature (as are the evolutionary sciences), that makes the discipline unfalsifiable and prone to just-so storytelling. But if that were the case, *all* disciplines with a historical component – including, for example, astrophysics, cosmology, and geology – would be exercises in just-so storytelling. This is obviously incorrect. Whether or not a scientific discipline includes a historical component is not relevant in differentiating good science from just-

so storytelling. What *is* relevant is whether the scientists in a given discipline – regardless of whether that discipline includes a historical component – use their hypotheses to *generate novel predictions that can be tested in the present day*. If they skip this crucial step, they may be engaged in just-so storytelling. By contrast, if they use their hypotheses to generate and test novel predictions about previously unobserved phenomena, they are engaged in normal, productive science. It is the latter that characterizes most evolutionary psychological research (for full discussions, see Buss et al. 1998; Confer et al. 2010; Ketelaar and Ellis 2000; Lewis et al. 2017).

Misunderstanding 13: Natural Selection Has Stopped for Our Species, So Humans Are No Longer Evolving

The thirteenth misconception is that humans have stopped evolving because natural selection has ceased operating on our species. This erroneous line of reasoning points out that we have eradicated many diseases, and that modern medicine keeps humans alive when they would have surely died in ancestral populations. There are at least three reasons why this does not warrant the conclusion that humans have stopped evolving.

First, we have not eradicated all diseases. People still die of cardiovascular problems, sexually transmitted diseases, respiratory diseases, cancer, and plenty of other illnesses. Every year, about 800,000 children die from diarrhea-related problems *alone* (Center for Disease Control and Prevention 2015). It is true that WEIRD societies (Western, Educated, Industrialized, Rich, and Democratic; Henrich et al. 2010) have made great medical progress, but as a species, we are far from having eradicated all sources of death and disease. The vast majority of the world still suffers from many illnesses, some of which are fatal. And of course this is to say nothing of warfare, homicide, and other causes of death.

Second, even if we *had* eradicated all sources of disease, this would not imply the cessation of evolution. Recall that it is differential *reproduction*, not survival, that is the bottom line of

Thirteen Misunderstandings About Natural Selection, Table 1 Misunderstandings about natural selection vs. accurate alternatives

Misconception	Accurate alternative
Natural selection is random and so is evolution	Mutation is random, natural selection is nonrandom, and as a consequence, evolution is also nonrandom
Survival is the bottom line of evolution by natural selection	Differential reproduction is the bottom line of evolution by natural selection. Survival is tributary to reproduction, and when the two conflict, reproduction trumps survival
There is an agent doing the “selecting” in natural selection	There is no agent and no active “selection”. The process is blind and passive, and a more accurate term for natural selection would be “differential reproductive success”
Evolution is teleological – the process has a final goal, endgame, or <i>telos</i>	Evolution is not teleological and has no final goal, endgame, or <i>telos</i> . Natural selection is blind and cannot peer into the future
Evolution favors the “survival of the species”	Most evolutionists agree that group selection is a much weaker force than genic-level and individual-level selection. Adaptations do not routinely evolve to benefit groups, and the survival of species is not a goal of evolution
Natural selection builds perfectly designed biological mechanisms	Natural selection builds functional mechanisms that are often impressive but are nonetheless suboptimal. This is because there are several unavoidable constraints on the power of selection (e.g., time lags and trade-offs)
Evolution implies genetic determinism	Evolution does not imply genetic determinism. An evolutionary perspective highlights the centrality of the environment at every stage: the initial evolution of adaptations, their ontogenetic development, and their immediate activation in the present
Adaptations must be present at birth (or must develop very early in life)	Natural selection builds adaptations that “come online” at the appropriate developmental stage of life, not adaptations that are necessarily present at birth. Teeth and breasts illustrate this principle
The products or outputs of adaptations are fixed and unchangeable	Evolved mechanisms are flexible. Because environmental input is crucial to the products of adaptations, it is often possible to change the output by simply modifying the input (e.g., calluses)
You can use the principles of evolution to predict behavior directly, bypassing psychological adaptations	Information processing is the key intervening step between the principles of evolution and predictions about behavior. Skipping this step can lead to errors in both prediction and explanation
Natural selection is the only driver of evolutionary change	There are four drivers of evolutionary change: mutation, migration, genetic drift, and natural selection. Natural selection is very important, and it is the only viable explanation for the structure and function of <i>adaptations</i> , but it is only one of four drivers of evolutionary change
Evolutionary hypotheses are inherently unfalsifiable “just-so” stories	Most evolutionary hypotheses are eminently falsifiable. When researchers use the top-down approach to generate <i>a priori</i> predictions, the “just-so” charge falls flat. When researchers use the bottom-up, observation-driven approach, whether the charge falls flat depends on whether the researchers use their hypotheses to generate novel, testable predictions. For an extended discussion, see Buss et al. 1998; Confer et al. 2010; Ketelaar & Ellis 2000; Lewis et al. 2017
Humans have stopped evolving because natural selection has ceased for our species	Humans are still evolving and natural selection is still ongoing in our species. We have not eradicated all sources of death and disease – and even if we had, the bottom line of evolution is differential reproduction, not survival. As long as some humans still reproduce more than others, natural selection is still ongoing in our species

evolution (see Misunderstanding #2). As long as some humans are still reproducing more than others, natural selection is still operating. This means that, putting survival aside, there are

plenty of sources of selection still operating on our species: mate competition, mate selection, mate retention, romantic infidelity, childrearing, investment in genetic relatives, grandparenting,

altruism, social betrayal, free-riding, status hierarchy negotiation, and more. Eradicating disease does not remove important selection pressures related to social processes, mating processes, and differential reproductive success. Indeed, not only are humans still evolving, but the pace of our evolution has *sped up* over the last 10,000 years (Cochran and Harpending 2009).

Third, it is important to remember that there are three prerequisites for evolution: (1) variation (organisms in a population vary), (2) inheritance (some of this variation is passed on to offspring), and (3) differential reproductive success (as a result, some of these organisms reproduce more than others). As long as ingredient #3 (differential reproductive success) still obtains, natural selection is still operating. And as long as *all three* prerequisites are still in place – as is the case among humans – evolution is still occurring. Consequently, humans are still evolving, and will be for the foreseeable future.

Conclusion

The theory of evolution by natural selection is regarded by scientists as one of the most parsimonious, explanatorily successful, and predictively powerful theories in the history of science (Alcock 2009; Coyne 2009; Dawkins 2009; Dennett 1996; Dobzhansky 1973). Its parsimony and simplicity suggest that it should not be difficult to understand, but misconceptions still abound, even among scientists. There are likely several reasons for this, including insufficient educational exposure to the principles and findings of evolutionary biology as well as social and ideological biases that serve as impediments to understanding (e.g., Von Hippel and Buss 2017). Ironically, some of these errors may also be rooted in the fact that our evolved cognitive systems make it difficult for us to understand evolution correctly (e.g., Evans and Lane 2011; Legare et al. 2013; Shtulman and Schulz 2008).

This entry has tackled what we see as the 13 most important misunderstandings about evolution and natural selection (see Table 1). This list is not exhaustive. For example, due to space

considerations, we were unable to discuss such misunderstandings as the notion that something is good because it is natural, the intuition that natural selection must always lead to change, or the idea that evolution is “just a theory” (e.g., Dawkins 2009). Nevertheless, we have attempted to clear away the most common impediments to an accurate understanding of natural selection. We hope this entry helps readers to avoid these misunderstandings and to think about the process of evolution in a rigorous and clear-headed manner.

Thomas Cathcart

Mark McCoy

Bowling Green State University, Bowling Green, OH, USA

Synonyms

Author; Philosopher

Definition

Thomas Cathcart is a New York Times and international bestselling author who specializes in making philosophical reasoning more accessible for public consumption.

Introduction

Thomas Cathcart graduated with a degree in philosophy from Harvard University and went on to

have what he describes as a checkered career of jobs, all the while attending divinity schools. Thomas Cathcart has been a probation officer working the streets of Chicago, has performed similar duties with doctors for medical insurance providers, and was the COO of a hospital while he continued to study philosophy. Later, Cathcart would go on to write several philosophy texts, including his most recent book *The Trolley Problem: or Would you Throw the Fat Guy off the Bridge?: a Philosophical Conundrum* (Cathcart 2013).

Thomas Cathcart has spent his authorial career trying to present major topics in philosophical reasoning in a digestible and accessible manner. Cathcart's first published book, *Plato and a Platypus Walk into a Bar...* (Cathcart and Klein 2008a), utilizes humor and jokes as a method of breaking down and examining issues in a crash course of basic philosophical principals. Similarly, his second book, *Aristotle and an Aardvark Go to Washington* (Cathcart and Klein 2008b), uses a sense of humor and philosophy to digest the political sophistry and fallacious arguments seen in modern American politics. His third book, *Heidegger and a Hippo Walk Through Those Pearly Gates* (Cathcart and Klein 2009), is a historical walk-through of how philosophers from antiquity to today have thought about death. What is clear from Cathcart's writing is that he values making philosophy accessible to the general public.

On his blog on BigThink.com, Cathcart asks the reader the question: Why philosophize? He brings up this question in light of some sobering data that indicates that liberal arts majors (including philosophy) have been decreasing since the 1970s, with the percent of individuals majoring in philosophy today sitting at only 0.7 %. Cathcart compares studying philosophy to children going to summer camp. In this analogy, he asks us to consider the implications of children being asked not to have their cell phones. On the one hand, the camp is designed to allow kids to have natural experiences, and on the other, they would be deprived of devices that they are normally allowed and expected to use in their everyday lives. Cathcart considers his summer

camp experiences as a child, long before cell phones and the Internet were a reality, but where the existence of maps still made the necessity for nature survival training a moot point. At the end, he concludes that summer camp likely has several goals, and one of those goals may simply be to allow kids to have fun, while another goal may be to give kids an opportunity to experience life in the most basic way possible. It is in these experiences, Cathcart says, that we try to form ourselves in some way so that we connect with other people on the most human level. This is why, he argues, we philosophize: to understand how to think critically and in a manner that allows us to connect with other ways of thinking and with other people.

Conclusion

As an author, Thomas Cathcart appears dedicated to making philosophy relevant and accessible in a modern world. His work strives to be humorous while simultaneously asking deep questions about the way humans consider the world around them. The question of why philosophy is important appears to matter a great deal to Thomas Cathcart and his work endeavors to address that question.

Thorndike's Law of Effect

Ioulia Papageorgi
University of Nicosia, Nicosia, Cyprus

Synonyms

[Law of Effect](#)

Definition

A theory of learning proposed by Thorndike stating that responses closely followed by satisfaction are firmly connected to that situation and are more likely to be repeated when the situation occurs again. Responses followed by discomfort have their association to the situation weakened and are less likely to occur in similar situations.

Introduction

Thorndike developed a theory of learning through on the basis of this experimental research with animals. He represented the original Stimulus-Response (S-R) framework and considered that learning is the result of associations formed between stimuli and response. He placed emphasis on the role of experience in the strengthening/weakening of S-R connections (Connectionism) and posed that learning happens through trial and error (Ormrod 2016). Some responses eventually dominate because they become associated with satisfaction.

Development of the Theory

Thorndike introduced his theory of learning, termed as Law of Effect in his doctoral

dissertation (Thorndike 1898) undertaken at Columbia University under the supervision of William James. His theory emphasized the role of trial and error in the learning process and on the associations formed between SR connections.

His methodology involved the use of puzzle boxes in which he placed an animal (e.g., a cat). The puzzle box was enclosed but had a door that could be opened by the pressing of a lever inside the box. A hungry animal was placed in the box and a piece of food was left outside the box. Thorndike observed the animal's efforts to escape the puzzle box in order to reach the food and recorded how long it took for each successful escape. The animal would be trying to escape by reaching through the cage and scratching at the bars of the cage. At some point, it would press the lever by accident, and the cage door would open. Thorndike observed that with the repetition of this experiment, the amount of time and effort spent on ineffective activities (reaching and scratching) was reduced and the pressing of the lever occurred sooner. He plotted the escape times in a graph that he called learning curve. While the animals took some time to escape initially, Thorndike found that they became increasingly faster in successive repetitions of the experiment until the escape time stabilized. This resulted in an S-shaped learning curve.

He concluded that responses followed by positive consequences (satisfaction) are more likely to be repeated in a similar situation, whereas responses followed by negative consequences (discomfort) are less likely to re-occur in a similar situation:

"Of several responses made to the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected with the situation, so that, when it recurs, they will be more likely to recur; those which are accompanied or closely followed by discomfort to the animal will, other things being equal, have their connections with that situation weakened, so that, when it recurs, they will be less likely to occur. The greater the satisfaction or discomfort, the greater the strengthening or weakening of the bond (Thorndike 1911, p. 244)

Thorndike described this kind of learning as instrumental conditioning, as a response is likely to be repeated when it is instrumental in producing rewards (Thorndike 1905). Subsequent

experiments led Thorndike to later revise the Law of Effect (Thorndike 1935), as he found that punishment did not weaken S-R connections, it only inhibited their expression. He thus de-emphasized the role of negative consequences and concluded that punishment has an indirect effect on learning as the organism engages in other behaviors (e.g., crying), which interfere with behavior (Ormrod 2016).

Evaluation and Influence of the Theory

Critics of the Law of Effect have focused on the following aspects of the theory: the retroactive working of the effect, its philosophical implication, the identification of the effective conditions that cause learning, and the generality of the law (Waters 1934). Furthermore, the notion of the bond has been contested by subsequent research. Nevin (1999), however, posed that in the light of reanalyzing these findings, this notion remains viable. He concluded that research on resistance to change gives support to Thorndike's view that the strength of the bond depends on the magnitude of the satisfaction received (Nevin 1999).

Thorndike's pioneering experimental work on animal intelligence and the puzzle box methodology he used inspired B. F. Skinner to invent a variation of the puzzle box that he termed operant conditioning chamber (also known as Skinner box) and conduct experiments investigating learning under controlled conditions. This eventually led to the development of one of the most influential learning theories, Skinner's theory of operant conditioning.

Conclusion

Thorndike's theory of learning known as Law of Effect states that responses closely followed by satisfaction are firmly connected to that situation and are more likely to be repeated when the situation occurs again. It stemmed from his pioneering experimental work on animal intelligence. The Law of Effect has been very significant in the development of behavioral learning theory.

Threats of Sperm Competition

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Synonyms

[Fear of cuckoldry](#)

Definition

The competition between sperm of rival males when a female engages in double mating. This double mating can result in cuckoldry and so males have evolved several strategies to assure paternity. Sperm competition (in both physiological and behavioral manifestations) is a response to this threat.

Introduction

Sperm competition has been documented in several species, including our own, and reviews of that literature can be found under ► [“Sperm Competition Theory,”](#) ► [“Sperm Competition: Evidence in Nonhumans,”](#) ► [“Human Sperm Competition,”](#) ► [“Opposition to Human Sperm Competition,”](#) and ► [“Tactics to Solve Adaptive Problems of Sperm Competition,”](#) as well as other related entries. While several of these entries provide detailed evidence of the process or its effects on behavior, the impact of such competition or the threat it poses to fitness is usually described in vague terms.

Threat of Cuckoldry

The most widely cited threat from (and motivation for) sperm competition is Cuckoldry Risk (a man

who raises another man’s child rather than his own is investing in an individual that will add nothing to his genetic fitness). What is the extent of this threat? The best available evidence concerning the incidence/risk of cuckoldry comes from a meta-analysis conducted on 67 published papers on paternity testing (Anderson 2006). The rate of nonpaternity ranged from 14.3% to 55.6%. Anderson partitioned the sample into those with high paternity confidence and low paternity confidence and discovered that the average nonpaternity rate was 1.7% for the high paternity confidence group and 29.8% for the low paternity confidence group. What this research indicates is that there is a wide range of cuckoldry incidence in the human species and that males have evolved strategies to detect it. Indeed the men who had reason to question their paternity (low paternity confidence) had cuckoldry rates 15 times higher than the men who had high paternity confidence. This also indicates that men have developed cuckoldry detection strategies across the species. The threat of cuckoldry has loomed large throughout our evolutionary history.

Baker and Bellis (Pioneers of Research on Human Sperm Competition) were among the first to investigate the physiological and behavioral responses to the threat of sperm competition and showed that when men were unable to monitor their partners, their sperm counts increased to meet the possible threat (Baker and Bellis 1993). Other entries have detailed the ► [“Physiological Evidence for Human Sperm Competition,”](#) ► [“Psychological Evidence for Human Sperm Competition”](#) and the exacerbation of these responses in ► [“Sperm Competition Risk and Partner Abuse,”](#) illustrating how sperm competition has been a major facet of male behavior and has major consequences for females. Behaviorally, partner abuse may be the tip of the iceberg as men have evolved counter strategies to sperm competition. Because of the definition of sperm competition, the scope of this review will be limited to the time of potential insemination (the beginning of sperm competition) through pregnancy, as research suggests sperm competition continues to play a role. For consequences/behavioral sequelae of cuckoldry or sperm competition

after birth, see ► [“Paternity Uncertainty and Father-Offspring Conflict.”](#)

Behavioral Responses

Men may respond to sperm competition behaviorally through semen displacement (see ► [“Genital Evolution”](#)). Semen displacement is an evolved feature of human penis morphology, where semen from rival males is displaced from the cervical area of the vagina by the coronal ridge of the glans through deep, vigorous penile thrusting, allowing the resident male to substitute his semen for those of his rivals. Men have also been shown to change their thrusting behavior to increase semen displacement when there are cues of sperm competition (Gallup et al. 2003). This would essentially remove sperm competition by literally removing the rival male's sperm. In addition to semen displacement, men reacting to the threat of sperm competition are more likely to pressure their partners for sex or force sex (Goetz and Shackelford 2006). This would, first, remove the sperm of rival males, and second, deposit sperm from the male partner to compete. It is also assumed, due to the work of Baker and Bellis (1993) that the sperm count of this ejaculate would be much greater.

Postconception Responses

The threat of sperm competition appears to extend past conception, as there appears to be a pregnancy termination strategy males unwittingly employ when sperm from a rival male is present in a pregnant woman's reproductive tract. Tremellen et al. (2000) reported that pregnancy rates were lower among couples who resumed intercourse shortly after undergoing in-vitro fertilization and speculated that coitus-induced intrauterine contractions could have resulted in implantation failure. This adds more depth to the displacement behaviors discussed above, as more vigorous thrusting may interfere with embryo implantation.

There is also the issue of pregnancy complications that occur when another man's seminal fluid is present in the reproductive tract. Dekker et al. (1998) identified changes in paternity (the father of the pregnancy's seminal fluid vs. another male's) as playing a role in preeclampsia. Women who have limited exposure to the father's semen are at an elevated risk for preeclampsia (Robertson et al. 2003) and preeclampsia is more likely in pregnancies from artificial insemination, where sperm are separated from seminal fluid (Koelman et al. 2000). Treating women who suffer recurrent miscarriages with paternal seminal plasma has been found to increase pregnancy success (Stern and Coulam 1993), and the risk of preeclampsia is reduced by repeated semen exposure over time (Klonoff-Cohen et al. 1989). This implies that it is not only exposure to semen that aids in pregnancy maintenance but consistent exposure to the father's semen may also be important. For this to be possible, the body must be able to make the distinction between different ejaculates and react to sperm from the non-paternal (competing) male in a way that threatens the pregnancy. Researchers have yet to discover this mechanism.

This isn't the first time we have seen sperm competition affect semen chemistry, or semen chemistry affect females. In their now classic paper, Chapman et al. (1995) found that sexual activity actually reduced lifespans in female *Drosophila*, due to male seminal fluid products that possessed spermicidal properties. Human ejaculate also contains spermicidal compounds (Jones et al. 1979) and there are also documented effects of human seminal fluid and seminal compounds that affect implantation, immune responses, and other facets of female physiology and psychology (Burch and Gallup Jr. 2006). We do not know the full extent of seminal fluid effects on females, and we also do not know the effect of sperm competition itself (or seminal fluid from two males) in the female reproductive tract. Baker and Bellis (1988) only examined the effect of sperm competition on the sperm who were competing. More research needs to be done on the physiological effects of sperm competition in women.

Postconception responses to sperm competition may also be behavioral. Researchers have long discussed intimate partner abuse during pregnancy and many question why a man would abuse his partner while she was pregnant (Hilberman and Munson 1978). One of the major issues overlooked on this topic is that of sperm competition or cuckoldry. When sperm competition is taken into consideration, it becomes apparent that the father of the pregnancy may suspect cuckoldry and may not believe the child is actually his. In fact, some reports from battered pregnant women suggest that their partner suspected that he was not the child's father, regardless of actual paternity (Campbell et al. 1992). Burch and Gallup (Burch and Gallup Jr 2004) found that among convicted spouse abusers, the frequency and severity of abuse doubled when the woman was pregnant. The men who abused their pregnant partners not only reported greater sexual jealousy, they suspected the unborn child was not theirs and much of the violence was directed at the woman's abdomen.

The Threat of Sperm Competition to Women

This brings up the important point of how sperm competition, and male responses to sperm competition, affects women. Perhaps this is the largest threat of sperm competition, as sexual jealousy and anti-cuckoldry tactics can be dangerous, even lethal to women. Almost half of all instances of homicides of females are perpetrated by their male partners (Fox 2005) and the rates of intimate partner homicide of females are approximately four to five times that of males (Campbell et al. 2007). Sexual jealousy has been described as one of the most frequent motivators of domestic assault (Wilson and Daly 1996) and control of female sexuality has been documented all over the world (Wilson and Daly 1998). It is because male sexual jealousy is a well-documented trigger for violence that some researchers claim that a male partner is the most dangerous person in a woman's life (Browne 1993).

Conclusion

In reviewing the literature, we see that most research on sperm competition is conducted from the male perspective (the goal of preventing cuckoldry); motivation for sexual behavior, semen displacement, sexual jealousy, and paternal uncertainty. However, the vast majority of male responses to sperm competition also have dangerous consequences for women. Male responses to sperm competition can include attempts to shift female physiology, rough sexual behavior, sexual coercion, chemical and physical attempts to terminate pregnancies, sexual jealousy, intimate partner violence, and even homicide.

Three Stages of Habitat Selection

Gordon H. Orians

University of Washington, Seattle, WA, USA

Synonyms

[Environmental aesthetics](#)

Definition

Habitat selection is the process by which organisms choose the places they might occupy and use for some period of time.

Introduction

Choosing a place in which to live is one of the most important decisions most animals make. An evolutionary approach suggests that individuals should evolve an ability to recognize environments in which they function well, to prefer them, and to recognize and avoid less suitable environments (Orians 1980). That is, the neural systems that motivate positive and negative responses to environments are evolutionary outcomes of a complex process that includes perceiving things and spaces, selectively extracting information from them, and reacting to them in terms of their potential utility. Given their diverse ecological needs, the criteria animals use to select habitats vary enormously. These processes do not require conscious evaluations; in the vast majority of species they proceed unconsciously. Human habitat selection, however, does involve

conscious decisions, so investigators have developed concepts that apply uniquely to our species. Habitat selection is usefully conceived as a three-stage process (Orians and Heerwagen 1992). Although the stages may overlap, their identification helps us think more clearly about the entire process.

Stage 1 begins with an encounter with an unfamiliar landscape. Abundant evidence indicates that these initial emotional responses are rapid and unconscious. During this stage an individual decides either to explore the landscape or to move on. If a Stage 1 response is positive, an individual enters Stage 2, during which it explores the area and gathers more information about it. If its exploration and assessment is positive, the individual may decide to stay in the environment. It then enters Stage 3 and makes another set of decisions about how to use that environment.

The assessment process is based on affordance, that is, what the environment offers, both positively and negatively, to an individual if it settles in it (Gibson 1979). Because bad choices were often costly, individuals would have benefited from developing error-detecting mechanisms that check the results of their perceptual calculations.

Stage 1

Although Stage 1 decisions do not require conscious inference, much unconscious processing may occur, especially if the current environment shares features with previously encountered ones (Kaplan 1992). General features of the environment, such as spatial configurations, depth clues, water, and trees (Kaplan and Kaplan 1989), typically trigger people’s rapid Stage 1 responses. Depth clues facilitate rapid assessment of distances. They help determine the time required to cross potentially dangerous open spaces and distances to potential prey or places offering protection. Water and trees provide useful information about food, location of safe sites, and movement

options. In other words, although the rapid responses made at Stage 1 are unconscious, they have evolved to be influenced by elements of the environment that signal its suitability for occupancy.

Our ancestors made many Stage 1 decisions during their lives. Investigators have inferred how our remote ancestors responded and the legacies of their responses by studying how we assess unfamiliar environments today. People quickly and unconsciously draw inferences when shown scenes of unfamiliar landscapes using two types of information (Kaplan 1992). One concerns what we need to know to *understand* and *explore* the scene. The other concerns how much information we need to process to draw *inference*s about it (Table 1).

Coherence refers to the ease with which a person can grasp a scene’s organization. *Legibility* is an assessment of how well one could find one’s way in it without getting lost. A *legible* space is one with a structure that enables individuals to navigate within it and find their way back to the starting point. To assess *complexity* people respond to objects that may tell them about the scene’s resource-richness.

Prospect-Refuge Theory. Aestheticians have long recognized that expansive views (prospects) enhance the attractiveness of landscapes, but an evolutionary perspective was needed to inspire British geographer Jay Appleton to develop prospect/refuge theory (1975). Appleton’s theory uses three features of a landscape – prospect, refuge, and hazard – to explain which features increase the likelihood that the individual will make a positive Stage 1 decision. Appleton conceived his theory while reading a paragraph in Konrad Lorenz’s classic book, *King Solomon’s Ring* (Lorenz 1952) in which, while strolling through a forest on a spring morning, Lorenz approaches a glade, pauses and reflects on how pleasant it is to see without being seen, that is to learn valuable things about an environment while concealed.

Three Stages of Habitat Selection, Table 1 The environmental preference matrix (After Kaplan 1992)

	Understanding	Exploration
Immediate	Coherence	Complexity
Inferred	Legibility	Mystery

Prospect offers a good view or vista. *Refuge* provides cover from which to observe and assess the environment. *Hazard* refers to the risks an individual faces while exploring the environment. These features may be available from the viewer's current position or only after it enters the environment. Elements of prospect-refuge theory are relevant to both our unconscious initial responses to unfamiliar landscapes and for the conscious assessments we make while exploring an area.

Appleton's ideas have influenced investigators across diverse disciplines. Appleton himself suggested that many features of landscape paintings could be understood by assuming that painters wished to induce viewers to imagine entering, exploring, and using the pictured environment. As predicted, he found that most of the landscapes they painted would be easy to explore in low risk ways and that they had places that offered good prospects and refuges (Appleton 1975).

Prospect-refuge theory also predicts that painters should alter actual scenes to emphasize places offering good views and refuges and indicate low risk passages. These predictions were tested by assuming that John Constable's sketches showed the actual scenes and that he made changes in the final paintings (other than those that refined it) to improve the attractiveness of the scenes. As predicted, Constable frequently added houses, people, and animals; he altered vegetation to open views to the horizon or to distant refuges, and made water features more conspicuous. He often added trees to the foreground, framing the picture, creating an impression that the observer was in a refuge where it was possible to see without being seen (Heerwagen and Orians 1993).

Many experiments have shown that although there are regular and meaningful patterns to our rapid evaluations of unfamiliar scenes, we are generally unable to explain our choices. When asked why we like or dislike scenes, we are embarrassed that we cannot explain why (Kaplan 1992), so we invent explanations (Haidt 2006). From an evolutionary perspective, it is not surprising that the brain processes and evaluates that information without our being aware of it.

Sex differences. Men and women should evaluate environments differently because during

most of human evolution men were hunters, women were gatherers. Women are less able to defend themselves when attacked; pregnancy and childcare would have made them especially vulnerable to predators and enemies. Therefore, women should have greater affinity than men for enclosures and protected places. Heerwagen and Orians (1993) tested this prediction by comparing prospect and refuge symbolism and locations of people in paintings by Irish and French female and male landscape painters. Women's paintings had higher refuge symbolism than men's paintings. Although men in the paintings were almost equally divided between prospect and refuge locations, the vast majority of women were within a refuge. Women were more likely than men to place both men and women in refuges. Although the differences are consistent with evolutionary expectations, painters were doubtless influenced by cultural factors as well.

Similar differences exist in the mental maps of men and women in other cultures. An Aivilik hunter's map of Southampton Island accurately shows the island's outline. Women's maps are composed of points that indicate locations of a settlement or trading post (Carpenter et al. 1959). Women in a farmer's market in California were better than men at remembering the locations of booths selling food. They remembered locations of booths selling high caloric density foods particularly well (New et al. 2007).

Stage 2

Cognition may be prominent during Stage 2 when an individual explores the area and gathers more information about it. Environmental features that command attention are primarily those that indicate the resource potential of the area and how safe it would be to use it (Berlyne 1971; Kaplan and Kaplan 1989; Kaplan 1992). But to gain that knowledge, explorers expose themselves to danger.

To avoid trouble while exploring an individual must recognize patterns, determine which ones signal danger, and respond appropriately (Coss and Owings 1985). Neural systems that motivate active escape from, and avoidance of, danger were probably among the first behavioral systems to

evolve in animals. The objects and situations that evoke fear were genuinely dangerous to our ancestors. A fear and learning neural circuit shared by many mammals, located in the amygdala (Öhman and Mineka 2003) yields rapid responses that can be triggered by very few clues (LeDoux 2000). In extreme form, these fears express themselves as persistent, seemingly irrational, phobias: *nature phobias*, *animal phobias*, and *social phobias*.

When we respond to a signal that may indicate danger we can make two kinds of mistakes. We can fail to respond when the danger is real, or we can assume that the danger is real when it is not. A false negative – failure to respond to a dangerous situation – is more costly than a false positive – responding to a situation that turns out to be harmless. The first error could be deadly; the second generally costs only wasting a bit of time and energy. This is why we have a negativity bias (Haselton and Nettle 2006), that is, we are more averse to losses than we are positive to gains (Kahneman 2003). We have more negative than positive emotions and have more words for pain than for good sensations (Rozin and Royzman 2001). We respond faster to threats and unpleasant events than to positive opportunities and pleasurable situations.

Other organisms are sources of food, fiber, and protection, but some of them – predators, parasites, and contaminated food – may be dangerous. Plants with sharp spines or irritating hairs are rooted to one spot, but most animals move around. Many animals are difficult to spot because they behave in ways to avoid being seen. Dangerous animals have been recognized for millennia; they are causes of many phobias, but we did not know of the existence of microorganisms until the twentieth century. We could not have evolved to fear them, but we do experience disgust when we see things that are associated with pathogens – pus, rotting meat, dead bodies, and feces.

Humans have evolved responses to features shared by many dangerous organisms. Predatory mammals have large, pointed canines and claws. Large herbivorous mammals have sharp horns, antlers, or hooves. African savannas are full of plants with sharp thorns and spines that can

puncture skin and eyes. Paying attention to those plants, especially during times of rapid movement, reduces the chance of injury. Richard Coss (2003) videotaped walkers and joggers as they passed two plants, one with sharp spines, the other without them. Both walkers and joggers favored the side of the path where the spiny plant was located; they passed close to it but did not touch it.

Venomous and constricting snakes have long been important vertebrate predators. Even today more than 150,000 people die from snakebites each year, most of them in the tropics. Other than lemurs, which evolved on an island lacking venomous snakes (Madagascar), all primates have an innately based fear of snakes (Isbell 2009). Laboratory-reared monkeys that have never seen a snake become fearful merely by observing other fearful monkeys or by viewing a fearful model monkey on videotape.

Our ancestors benefited from an ability to detect hidden, stationary predators from glimpses of only small parts of them. Special systems for distinguishing the patterns that provide camouflage (stripes, spots, tessellated patterns) and for detecting eyes evolved. We are especially sensitive to tessellated patterns, which are common among snakes but rare elsewhere in nature (Isbell 2009). Nine- to 10-month old human infants do not react differently to snakes than to other animals, but by the age of 1 year, before they begin to walk, infants quickly associate snakes with fear (DeLoache and LoBue 2009). By the age of three, children detect snakes more rapidly than nonthreatening stimuli (flowers, frogs, caterpillars). In contrast, neither children nor adults detect a single frog among flowers better than a single flower among frogs (LaBue and DeLoache 2008).

People of all societies studied by scientists dream about snakes (Mundkur 1983). Dreams of urban New Yorkers, most of whom have never seen a snake are as detailed and emotional as those of Australian aborigines and Zulus, most of whom probably had repeated contact with venomous snakes. Worldwide, snakes and snake-like creatures have mystical significance and are dominant elements of dreams in which animals of any kind appear.

People have perceptual biases that direct their attention to other hazardous situations. For example, uneven ground may be dangerous because a trip can result in an injury that makes it harder to walk; falls of only a meter or two can produce serious injuries. These risks were especially important when our ancestors were pursuing prey or escaping from enemies. Our perceptual system makes vertical surface irregularities seem larger than they are (Jackson and Cormack 2008).

Stage 3

After exploration and assessment, an individual may decide to stay in and use the environment in a variety of ways. It may improve the environment (e.g., dig burrow, build a dam, erect a shelter, clear brush, dig a well) and make decisions about how to use the habitat and the varied patches that comprise it. Which patches should it visit, when, for how long, and for what purpose? These decisions may influence an individual's success over markedly different time frames. A decision about whether to attack a prey item typically affects an individual's behavior for only a few seconds; it may have a minuscule effect on survival and reproductive success. In contrast, a decision about where to build a nest or dig a burrow may influence behavior for a long time and have major fitness consequences.

We can classify information in terms of its relevance to the time frames of major decisions that humans make about how to use an environment (Table 2). Some information signals current events whose significance will quickly pass. Responses to such information must be rapid and decisive. Humans are highly attentive to such information. Other information highlights seasonal environmental changes that are associated with present and future locations of resources. This information is most relevant to decisions, such as when to move a camp that can be made after considerable reflection, evaluation, and discussion.

Assessing the current and long-term food-provisioning capability of an environment is an important part of evaluation during Stage 2 of habitat selection; these assessments also dominate

many Stage 3 decisions. Foraging evolved to be emotionally satisfying because those of our ancestors who did not enjoy seeking food probably left fewer surviving offspring than those who did enjoy it. Also, a successful hunter, by virtue of his success often benefitted socially and sexually (Hawkes 1990). We hunt, fish, and gather berries today even though comparable food is available in stores at much lower prices. Catch-and-release fishing is a rapidly growing sport because many people who do not eat fish nevertheless enjoy fishing!

To find animals, hunters use clues they leave in the form of tracks, feces, damage to vegetation, and remains of kills. Hunters in traditional societies are famous for their remarkable tracking abilities. The skills and predispositions involved in cognitive processing of animal tracks appear to reside in the basic architecture of our brains today. City dwelling people recognize and remember animal tracks more readily than they remember nearly all other types of visual stimuli (Sharps et al. 2002).

A few of the plants humans eat have edible tissues throughout the year. Although they are stationary, remembering the location of specific individuals facilitates when and where to find tender leaves, flowers, and ripe fruits. Leaves vary not only in the hue and saturation of their dominant green color but also in variegated patterns of other colors. A legacy of the value of paying attention to colors of plant tissues is readily apparent during a visit to any modern nursery. Plant breeders have favored mutants of ornamental plants with different overall colors (yellow-green, gray, or blue), variegated patterns, and leaves with different colors on their upper and lower surfaces. Breeders have also favored mutants with leaves that have contrasting colors at times of years when leaves of most plants are green. Mutants of garden trees with atypical leaf colors, even those that produce neither striking flowers nor edible fruits (such as maples), have been strongly favored by plant breeders. Mutants of conifers with yellow, variegated, and blue-gray leaves also are popular among horticulturalists (Orians 2014).

Watching bees visiting flowers helps people find honey, and know where fruits and seeds will be found in the future. In species-rich vegetation,

Three Stages of Habitat Selection, Table 2 Temporal relevance of environmental information

Temporal category	Examples	Decisions affected
Short-term (minutes to hours)	Weather changes (thunder, clouds, wind)	Seeking shelter, initiating or terminating outdoor activities
	Appearance of dangerous animals or enemies	Immediate defensive or evasive actions
	Appearance of prey	Immediate hunting decisions
	Illumination changes	Moving to an appropriate location for spending the night or for daytime foraging
Seasonal	Day-length changes	Shifts of hunting sites, planting, and harvesting of crops
	Vegetation growth	''
	Flowering	''
	Precipitation changes	''
Multiyear changes (decadal)	Vegetation succession	Shifts of hunting sites, movement of villages
	Erosion (river meanders, lake sedimentation)	
Long-term (decades to centuries)	Topography	Constrains many kinds of decisions

flowers greatly aid in identifying plants that otherwise may be difficult to distinguish among masses of similar green leaves. An evolutionary legacy of this value is our fascination with flowers. As far back as we have records people have cultivated and used flowers.

Once found foods might still not be worth pursuing. A normally edible item might be infested with pathogens. Charles Darwin (1872) was the first person to identify the strong relationship between food and disgust. Disgust, which is expressed in all human cultures, is the most powerful reason people reject certain types of food. Disgust is an adaptation that deterred our ancestors from eating animal tissues likely to harbor harmful microorganisms. Microorganisms can multiply rapidly; there is no dose below which it is safe to ingest them. Responses to potential contamination are, appropriately, dose insensitive. Disgust is evolutionarily programmed intuitive microbiology that developed long before people knew that microorganisms existed, much less that they caused diseases. Although plant tissues are generally less nutritious and more difficult to digest than animal tissues, they are much less likely than animal tissues to harbor toxic bacteria. They rarely evoke disgust, but most “inappropriate” foods are plant tissues (Rozin and Haidt 2013).

Conclusion

A rich and expanding literature shows that our varied emotional responses to the physical and biological environment today are, in part, a legacy of the way our ancestors made important Stage 1, 2, and 3 decisions in African savannas and the consequences of those decisions for survival and reproductive success. Environmental challenges were a dominant part of their lives. How they responded to those challenges was often a life-or-death matter.

An evolutionary perspective also suggests why the structure of human thought is binary. Most of the decisions of our ancestors had “either-or” answers. An object or landscape was either to be approached or avoided. A perceived object was either food to be eaten or to be rejected. The appropriate decisions often had to be made quickly. Although taking action requires quick and binary decisions, inputs from the environment are often complex and contradictory. Our brains tend to resolve complex events and inputs into polar categories, which is necessary if appropriate action is to be taken in a timely manner. Claude Lévi-Strauss claimed that all tribal myths are built upon binary opposites (Levi-Strauss 1962). Spatial distinctions in most languages are either-or. The universality of these patterns suggests that polar typology has deep evolutionary roots.

The body of information on human responses to the environment is impressive and growing rapidly, but it is only the beginning of what is certain to become a mature science of the evolutionary psychology of habitat selection. Most tests so far have involved people in only a few cultures. Much more crosscultural and age-related research is needed to determine which of these responses are universal and which are culture-specific.

Definition

The four levels of explanation at which Tinbergen (1963) argued that a behaviour can and should be understood.

Introduction

In one of the founding texts of the field of ethology, *On Aims and Methods of Ethology*, Niko

Tinbergen (1963) proposed that a complete understanding of any given behavior necessitates explanation at four different levels (the “four major problems of biology”): causal (or mechanistic), ontogenetic, phylogenetic, and functional. These levels of explanation have variously been referred to as Tinbergen’s four questions and Tinbergen’s four whys. They can be further classified into proximate (causal/mechanistic and ontogenetic) and ultimate (phylogenetic and functional) levels of explanation, distinctions originally proposed by Ernst Mayr (1961). Proximate levels of explanation consider the mechanisms of how a behavior is produced, while ultimate explanation accounts for why, from an evolutionary perspective, the behavior exists (Tinbergen 1963). This entry will define these levels and briefly discuss their significance for evolutionary psychology.

Causal/Mechanistic Explanations

Causal, or mechanistic, explanations for behavior consider the immediate neurophysiological, hormonal, psychobiological, and environmental causes of a given behavior. Such explanations often concern the necessary and sufficient conditions required to produce the behavior. For example, causal/mechanistic explanations for breastfeeding could refer to the roles of prolactin and oxytocin in milk production and letdown, the role of physical stimulation on the breast and nipple that promotes oxytocin production, and the relationships between breastfeeding and a mother’s heightened neurophysiological response to the sound of her own baby crying (Jonas and Woodside 2016).

Ontogenetic Explanations

Ontogenetic explanations for a behavior concern the development of the behavior across the life span, including cognitive development, learning, and other experiential effects. Ontogenetic explanations for breastfeeding might include the role of early mother-infant bonding and the importance of initial breastfeeding attempts (Jonas and Woodside 2016). Ontogenetic explanations also

encompass much more long-term experiential influences on behavior, such as learning experiences surrounding breastfeeding during the mother's own development (Hoddinott and Pill 1999).

Phylogenetic Explanations

Phylogenetic explanations for behavior consider the evolutionary history of the behavior: as it manifests in the extant species in question, and how this has changed over evolutionary time, across multiple speciation events. It frequently includes consideration of exaptations (where structures originally selected for one purpose become co-opted for a different purpose in subsequently evolving forms). Our breastfeeding mother may be understood as breastfeeding her child because humans descended within the mammalian clade and thus inherited the physical (mammary glands, nipples) and physiological (oxytocin and prolactin neuroendocrine pathways) structures that support breastfeeding from ancestors in whom these structures appeared more than 160 mya. A phylogenetic explanation may also consider that mammary glands likely evolved from reptilian abdominal epidermal glands, which were exapted for nutritional purposes as newborn lizards acquired nutrients and immunologic compounds from their secretions (Goldman et al. 1998).

Functional Explanations

Functional explanations of behavior (also referred to as adaptive significance, or current utility, Bateson and Laland 2013) consider the survival value (and ultimately, the reproductive value) of the behavior. They seek to describe the selection pressures that lead to the emergence, shaping, and maintenance of behaviors over evolutionary time. As such, breastfeeding can be understood as evolving in response to selection pressures to provide nutrients and immunocompetence to offspring. In humans, at least, it has also likely been shaped to serve mother-infant bonding functions (Jonas and Woodside 2016).

Tinbergen's Four Questions in Psychology

While much of the discipline of psychology is traditionally focused on proximate explanations of behavior, ultimate, especially functional explanations are the level of explanation most often associated with evolutionary psychology. Tinbergen, however, was clear in his argument that any given behavior can be simultaneously understood at all four levels of explanation, and indeed to fully understand the causes of any behavior, it is necessary to incorporate complete explanations at all four levels (Tinbergen 1963). Indeed, the key insight of Tinbergen's 1963 essay was not simply the content of the four levels of explanation but the complementary and integrative nature of them (Nesse 2013). In spite of its traditionally strong focus on ultimate questions, the discipline of behavioral ecology has more recently shifted toward an appreciation of the importance of integrating explanations across the four levels of explanation (Bateson and Laland 2013). Such integration, however, is still less common within the broader discipline of psychology (Sulikowski and Burke 2015).

Critics of evolutionary psychology (and of adaptive and biological explanations of human behavior more broadly) often mistakenly presume that different levels of explanation are mutually exclusive and competitive. Much confusion, in particular, surrounds the proximate/ultimate distinction. Stephen Jay Gould, for example, argued that "the [*ultimate*] question, 'what is it for?' often diverts attention from the more mundane but often more enlightening [*proximate*] issue 'how is it built?'" (Gould 1981). Rose and Rose (2001) protest that evolutionary psychologists "insist on... ultimate... explanations when proximate ones are so much more explanatory" (p. 4). Persistent misunderstandings about the complementary nature of proximate and ultimate explanations currently impede an integrative application of Tinbergen's four questions to understanding human behavior.

To return to our breastfeeding mother, critics of evolutionary approaches to behavior may argue that an understanding of the behavior may be satisfactorily provided by a description

of the stimulus (her infant crying) and associated neural and hormonal responses to the stimulus [a *causal* explanation] and of the experience and learning surrounding breastfeeding during her own development [ontogeny]. A Tinbergian understanding, however, demands that we also consider the evolutionary history [phylogeny] of breastfeeding, perhaps through the lens of comparative psychology, and the *functional* value of breastfeeding in providing nutrients and immunocompetence benefits to the infant in order to help him survive and develop successfully in order to pass on his mother's genes to the next generation.

Conclusion

While evolutionary psychologists and other researchers who take an evolutionary approach to understanding human behavior provide valuable insight into the ultimate causes of behavior, it has been argued that adopting a formal Tinbergian framework, considering a behavior at all four levels of explanation, can provide a fuller understanding of the behavior in question (Stephen et al. 2017).

To Afford Protection Against Climate and Weather

Definition

Humans invented clothes as artificial protection from cold to compensate for the loss of body fur

which became a critical survival issue during the Pleistocene ice ages. The physiological function of clothing as thermal insulation is reviewed, along with archaeological evidence for the development of complex clothes and later textile fabrics as adaptations to changing climates.

Introduction

Adaptation to the thermal environment is crucial to the survival of all living things. Extremes of heat and cold exert selection pressures on animal species, resulting in both biological and behavioral adaptations to climate.

Primates are generally adapted to life in warm climates and early hominins evolved in the tropics of Africa. A number of unusual traits – upright posture, sweating, and the loss of body fur – may reflect adaptation to the dry heat of the African savanna (Ruxton and Wilkinson 2011).

Human evolution is an enigma in this regard. Loss of fur – biological nakedness – deprives a mammal of natural protection against cold weather, yet *Homo sapiens* evolved in the environmental context of the Pleistocene ice ages. Human nakedness mystified Darwin: he could see no advantage in terms of natural selection and suggested it might be a case of sexual selection (Darwin 1871).

Hominins began to spread outside the tropics during warm interglacials. Over the last million years, they developed a series of behavioral adaptations to compensate for their biological vulnerability to cold. The main strategies were control of fire, use of shelter, and the manufacture of clothing. Fire was utilized as early as 800,000 years ago (Walker et al. 2016). While fire and shelter facilitated a hominin presence in cooler climates, only clothes could provide the portable protection necessary for a sustained occupation of cold climates.

Human Cold Tolerance

The human body begins to react to cold at an air temperature of +27 °C (80 °F). At +20 °C, the

metabolic rate begins to climb to generate extra heat, and shivering (a sign of failure) starts at +13 °C. This susceptibility is due mainly to lack of fur: rabbits for example can survive at –45 °C but when shorn, they start to struggle at 0 °C. People can become acclimatized to cold, as seen among those who work in Antarctica: after a few months they manifest an attenuated metabolic response to cold exposure. Clothing plays a paradoxical role: with regular use of clothes from birth, humans habituate to a warm microenvironment and hence become more sensitive to cold. For this reason, hunter-gatherers who are routinely naked have better cold tolerance. The safe naked limit for brief exposure (up to an hour or two) is around 0 °C, extending to as low as –5 °C for foragers like Australian Aborigines who led a traditional lifestyle without clothes. By mammalian standards, human physiological adaptations to cold are distinctly inferior (Jessen 2001).

Hypothermia

The core temperature of the human body must remain within a few degrees of 37 °C. Hypothermia begins at 35 °C and at 33 °C people begin to experience blurred vision and lose consciousness. Below 30 °C is severe hypothermia when blood pressure falls and the heart rate slows, with cardiac arrest inevitable by 15 °C. Depending on variables like age, physical fitness and alcohol consumption, as well as environmental conditions such as wind, survival times for humans with hypothermia vary between 1.5 and 12 hours. At an air temperature of –10 °C, the survival time for people without clothes is 3–6 hours (Dettmeyer et al. 2014).

Frostbite

Frostbite is the other main danger, though it is less commonly fatal. Frostbite primarily affects extremities like fingers, toes, and ears, and it can cause tissue loss and gangrene, which sometimes leads to infection and death from septicaemia. As with hypothermia, the safe exposure times are determined by wind as well as air temperature. At an air temperature of –15 °C and a wind speed of 40 km/h, symptoms of frostbite can develop within 30 minutes (Ducharme and Brajkovic 2005).

Climate Variables

Air temperature and wind are the most salient aspects of climate, along with moisture (rain, snow and humidity); intensity of solar radiation – which varies with latitude – and cloud cover are additional factors. Seasonal and diurnal ranges need to be taken into account when using mean annual values from meteorological data. Also relevant when considering evolutionary adaptations are the likelihood of extreme conditions, which may occur infrequently but which may ultimately determine survival chances.

Temperature

When the temperature of the environment is lower than skin temperature (typically 35 °C), heat is lost from the skin surface to the surroundings. Thermal conductance increases from gaseous to liquid and solid states: water for example has 24 times the thermal conductance of air. Skin cools more rapidly in liquids and more so when in contact with solid surfaces – hence liquids and solids feel colder (and cause more rapid heat loss) than air at the same temperature. This differing conductivity is the basis of thermal insulation with clothes, which trap air near the skin; this is also why moisture is a major problem for clothes.

The thermal comfort zone for modern humans with clothes is generally 21–24 °C. Infants are more susceptible to cold, and when naked they can begin to develop hypothermia at 33 °C.

Wind Chill

Any movement of air against the skin surface removes body heat, and the presence of moisture (either on the skin or in clothes) exacerbates heat loss with wind due to evaporative cooling. At low air temperatures, the cooling effect of wind is exaggerated: even moderate wind speeds increase the dangers at sub-zero air temperatures, as seen with the wind chill index (Osczevski and Bluestein 2005). Superior protection from wind is afforded by fitted (or ‘tailored’) garments.

Environmental Moisture

The thermal conductance of fluids means that moisture in any form compromises the thermal

effectiveness of clothes. Moisture also displaces air, and its evaporation extracts heat from the skin – which is how sweating operates as a cooling mechanism in warm climates. Even in cold climates however, perspiration still occurs and its production increases with physical activity. Higher levels of relative humidity in the environment will reduce the capacity of air to absorb sweat and thus impede the evaporation of sweat. Humidity therefore reduces the cooling capacity of sweating and when wearing clothes, it causes sweat to accumulate. For these reasons, clothing functions best in dry climates.

Clothing Physiology

The insulation value of clothing as protection from cold derives from trapping still air close to the skin surface; all other considerations (such as the material) are secondary. Clothes are of limited value as insulation from heat in hot climates: garments can protect from direct solar radiation but any such benefits are outweighed by impediments to convective and evaporative cooling. To reduce the disadvantages, clothes in warm climates should be loose and made from light woven fabrics, with a minimum number of layers.

Principles

Fitting refers to the shaping of a garment to closely enclose the body. Insulation is further improved with separate cylinders to enclose the limbs (which have a relatively greater surface area and hence higher potential for heat loss). Not only does this result in improved trapping of air, fitting provides more protection from wind penetration and wind chill.

Layers provide additional insulation, since the inner layers are protected from air movement. Modern garments are generally fitted and layers require fitting (at least for inner garments), so the emphasis with cold weather apparel is on layers. Clothing zones are defined based on the minimum number of layers required: the Arctic region for example is designated as a four-layer clothing zone.

Woven fabrics allow perspiration to escape through the material whereas animal skins and

furs are less permeable. Leather may be favored for footwear due to its durability but sweat is always an issue, so running shoes for instance are made from woven material.

Measuring the Thermal Value

Thickness gives an approximate measure of insulation, corresponding to the amount of trapped air. For example, a 50 mm four-layer assemblage can enclose nearly half that radius of trapped air.

Clo units are the commonest scientific measure:

$$1 \text{ clo} = 0.155 \text{ m}^2 \text{ K W}^{-1}$$

(m^2 = surface area, K = °Kelvin, W = watts)

One clo unit corresponds to a typical modern garment assemblage (e.g., shirt and trousers, with underwear) for a person to be comfortable in a room at an air temperature of 21 °C, with modest air movement (0.1 m/s) and low relative humidity (<50 %). In general, each clo unit corresponds to a complete layer of clothes, and a full four-layer ensemble suitable for Arctic winter weather provides ~ 4 clo of insulation.

Climate and Clothing Evolution

Archaeological evidence indicates that hominins began to use simple clothes by the Middle Pleistocene, around 800,000 years ago. The materials were animal skins and furs and the basic Paleolithic technology was the stone hide-scraper. Toolkits dominated by scrapers became more common in middle latitudes as hominins occupied colder environments during glacial episodes from 400,000 years ago.

Complex clothes (fitted garments with the option of multiple layers) required further technological innovation: dedicated cutting tools (stone blades) and hide-piercing implements (awls and later eyed needles, often made from animal bones). These toolkits were a prerogative of *H. sapiens* and complex clothing was developed in cooler parts of Africa during a cold phase 75,000–60,000 years ago. Toolkits with blades and awls accompanied the subsequent spread of

modern humans into northern Eurasia from 45,000 years ago. Complex clothing gave modern humans an advantage over Neanderthals, whose scraper-dominated toolkits suggest they had only simple clothes (Gilligan 2007). By 28,000 years ago as the climate deteriorated towards the Last Glacial Maximum (LGM), modern humans with these clothing-related tools – including eyed needles – had reached northeast Siberia (latitude 70°N), when the average winter temperature is estimated at –50 °C (Kuzmin and Keates [in press](#)).

Textiles became the optimal material for clothes with global warming from 12,000 years ago, notably in agricultural communities where fiber resources such as wool, flax, and cotton were domesticated. Wind penetration was less of an issue whereas the woven structure allowed sweat to disperse (e.g., Tang, Chau, Kan, and Fan 2015) – a critical consideration in climates that were warmer and more humid.

Conclusion

The thermal properties of clothing were crucial to the evolutionary success of hominins, and the development of complex clothes allowed *H. sapiens* to spread into every climate zone on earth. Clothing is a behavioral compensation for biological nakedness and a uniquely human adaptation to past climate change.

Definition

Manipulating an object, by changing or modifying some property of that object, in order to make it function better as a tool.

Introduction

Tool use in animals is rare (despite the multitude of reports in the scientific and nontechnical literature; Shumaker et al. 2011). However, toolmaking is even rarer. Indeed, within the avian taxon, only two species regularly make tools in the wild, and three other species have been observed making tools in an experimental context in captivity. Only woodpecker finches (WF) and New Caledonian crows (NCC) use (some) tools that need to be

either detached or fashioned in some way before use, rather than being found in a perfect state in which they can subsequently be used. There is an argument as to what constitutes tool manufacture. Does removing a spine from a cactus represent toolmaking, or is this a simple environmental manipulation that allows objects to function as tools? A cactus spine is already in a form that aids its eventual use as a tool (i.e., it has a pointed end); the bird does not need to modify the spine in any way for it to function as a probing tool. However, it cannot be used as a tool when it remains attached to its parent cactus plant. Is detaching a spine therefore a case of toolmaking? Shumaker and colleagues (2011) consider it to be. By contrast, consider the less ambiguous case of a stick, either attached to or separated from a larger branch. To become a functional tool, the stick needs to be fashioned in some way (unless it is being used as a fly swat, such as by some elephants). Side twigs need to be removed, the main shaft may need to be shortened or sharpened, or the end sculpted into a hook. These are definitely actions designed to change the original object into something different and so unambiguous toolmaking.

Why do only two species regularly make tools and only within a foraging context (whereas chimpanzees make tools for a variety of purposes)? It is probably the result of the type of tool use employed by other main avian tool users (see Bird Tool-Use). For example, green herons use bait to lure fish, and Egyptian vultures drop stones onto ostrich eggs to break them. In neither case, does an object need to be modified in order to become a functional tool. A piece of bread or an insect can be used as bait, or a stone or rock can be used to crack open an egg; in both cases the original object works well as a tool in its original state (except in the case of maiming the insect so it cannot escape, which does not seem to be a case of toolmaking). NCC and woodpecker finches also use tools that need no modification, such as sticks without hooks, or cactus spines, but importantly they do change other (nonfunctional) objects into (functional) tools, such as turning a *Pandanus* leaf into a probing tool or a stick into a hook.

Likewise, there are three bird species that do not naturally use tools in the wild, but which readily do so in captivity. They each make or modify tools from different materials, but all within the context of acquiring food that is out of reach. The following section will discuss these five examples of avian toolmakers, how they create their different tools, and the advantages of creating or sculpting a tool rather than just using material without any modification.

Avian Toolmakers

Woodpecker Finches

Originally, WF were not thought to make tools, but only use natural found objects in their environment that could function as tools, such as cactus spines and small twigs. However, WF do detach both twigs and cactus spines and modify them (shorten or trim off side branches). Recently, WF were provided with nonnative blackberry bushes, and individuals removed blackberry twigs, using the barbs along the length of the twigs as hooks (Tebbich et al. 2012).

New Caledonian Crows

NCC create three types of tools; *Pandanus* leaf tools and stick tools, either with or without a hooked end (Hunt 1996). Original studies of tool-making extrapolated how they were made through the discovery of tool counterparts (i.e., the shapes left behind in the leaf after the tool had been made and removed) or the tools themselves. However, it was possible to view cases of toolmaking by setting up artificial foraging sites which could be closely observed and recorded. Hunt and Gray (2004a), for example, observed crows making hooked stick tools using a three-stage process. The crow selected the appropriate raw material (i.e., a branch of the correct length) and in the correct location to make a hook (at the fork between two twigs). One twig was removed above the fork in order to leave a hook at one end. This twig was trimmed of side branches and leaves, before sculpting the hooked end, removing small pieces of wood left from the break (see also

Klump et al. 2015, discussing the variety of hook tools based on the raw materials available).

Hunt and Gray (2004b) also observed crows making different tools from *Pandanus* leaves, basically confirming Hunt's (1996) earlier suggestion of how they were made. There are three main subtypes: wide, narrow, and multistep. In each case, a small tear is made at the edge of the leaf, making sure that one side of the tool utilizes part of the natural barbs present along one side of the leaf. Once the initial tear has been made (a small tear for a narrow or multistep tool, a longer tear for a wide tool), a strip down the length of the leaf is pulled (how long is dependent on the tool type); then another tear, either detaching the tool or part of a series of strips; and tears until a multistep tool is created.

Goffin's Cockatoos

A captive Goffin's cockatoo, Figaro, was discovered using a piece of bamboo to rake in a pebble he was playing with. In an experiment, Figaro made a series of tools, pulling long strips of wood from the wooden posts of his aviary in order to retrieve in a cashew nut that had fallen out of reach (Auersperg et al. 2012). In ten trials, he created nine different tools (one tool was ready-made). An assessment of the tools found some conformity in design (although this doesn't necessarily mean that he had a design "in mind" when he made them, rather that this was a constraint of the material and the method for making the tools, which resembled that of *Pandanus* tools made by NCC).

Northern Blue Jays

Similar to Goffin's cockatoos, Northern blue jays also do not use or make tools in the wild, but have been observed doing both in captivity. A caged blue jay was reported tearing strips of newspaper and pushing them through the bars of their cage to rake in food that had dropped out of reach (Jones and Kamil 1973).

Rooks

Rooks have only been observed making tools in captivity. Apart from hooks (see below), rooks

also modify tools to make them functional. For example, rooks were presented with a collapsible platform task (Bird and Emery 2009; see also Bird Tool-Use) in which a weight has to be deposited into a vertical tube to release a platform holding a treat. Four rooks had rapidly learned how the task worked by dropping stones, but then spontaneously dropped heavy sticks or inserted and then pushed down on lighter sticks to achieve the same effect. When rooks were presented with sticks already inserted into the tubes, but with side branches attached to stop them from passing through the vertical tube, they removed only those side pieces that prevented the sticks from becoming functional tools.

Sculpting Wire Hooks

NCC have been observed making hook tools (either using the barbs along the side of *Pandanus* leaves as hooks or fashioning hooks from the cutoff points of detached sticks; Hunt 1996; Hunt and Gray 2002; Klump et al. 2015). However, the discovery that a female NCC called Betty could bend straight pieces of wire into hooks to retrieve a bucket containing meat at the bottom of a tube was a revelation. Betty and her male partner, Abel, were provided with a straight piece of wire and wire already shaped into a hook. Abel stole the hook, but did not use it to retrieve the food. After a number of attempts at using the straight wire to reach the food, Betty then used the corner of the plastic tray the tube was standing in as leverage, to help bend the end of the wire into a hook and then used that end to pull up the bucket (Weir et al. 2002). She did this ten times in a more controlled experiment. Although the hooks were more bent in the wire to a shallow angle than true bends, they were successful in gaining the food. Of most interest is the fact that despite Betty's success in using the hooks, she continued to insert the straight wire, perhaps to spear the piece of meat in the bucket, as this had occasionally been successful.

Although this discovery was stunning, it is inside of the natural capabilities of this species, as they not only fashion hooks but also bend some raw materials into hooks (Klump et al. 2015). Betty had also been provided with a model hook to base her design around. The finding that four captive rooks also bend wire into hooks, however, is more intriguing. How could rooks make tools of this type when they don't even use tools in the wild? The rooks had previous experience of using wooden hooks to retrieve small buckets from the bottom of vertical tubes and had previously inserted sticks (and stones) into tubes resulting in the deposit of a reward. It is possible that despite wire being an unknown substance for making a tool, they could rapidly learn about its properties after inserting it into a tube and trying to use it as a hook. This could have created a small bend, and the feedback from this causes the birds to continue bending the wire until they made a hook. Interestingly, the birds then flipped the hook into a functional orientation before using it successfully (Bird and Emery 2009).

Conclusion

Despite the rarity of bird species that make tools, the case of NCC is presented as one of the most complex forms of tool manufacture of any non-human animal, and the special case of wire bending in both NCC and four rooks demonstrates toolmaking on a par with our early ancestors. Bending an object into a hook has never been observed in any of our primate relatives. Although wire bending, especially in a non-tool-using species, appears remarkable, the fact that only a few birds across a small number of trials did this raises questions about the underlying psychological processes involved in this complex behavior.

Tool Play

R. Adriana Hernandez-Aguilar

Centre for Ecological and Evolutionary Synthesis
(CEES), University of Oslo, Oslo, Norway

Definition

Entertaining interaction employing a tool.

Introduction

Primates use natural and human-made items during play. In play, a tool (*sensu* Shumaker et al. 2011) is distinguished from an object by having an immediate and evident purpose. Tool play can be solitary or social. In solitary play an individual plays directly with the tool. In social play more than one individual employ the same tool either to play directly with or as a signal to convey information about a game. Comparatively, there are fewer reports of tool play in monkeys than in great apes.

Evidence from the Wild

The following types of tool play behaviors have been reported for wild primates (Goodall 1986; Sabater Pi et al. 1993; McGrew 2004; Ramsey and McGrew 2005; Nishida et al. 2010; Kahlenberg and Wrangham 2010; Shumaker et al. 2011).

Chimpanzees

During social play chimpanzees drag sticks, aimed throw dead sticks at each other, and use sticks and grass to bat each other. When wrestling, sometimes youngsters use leafy branches to press on a playmate's body. In the "tug-of-war" game, two competing chimpanzees (or seldom two groups) pull an object at the same time but in opposite directions.

To solicit play, the most common behavior is "play-start": an individual invites another to play while holding an object (usually a piece of vegetation, but rarely other object such as a piece of monkey skin or termite mound or an ant nest) in

the mouth (but also in the hand, foot, or groin pocket), teasing and displaying it to the potential play partner, sometimes waving it. This initiates chasing, and roles can be inverted if the partner manages to steal the object. There are other behaviors to invite play: an individual shakes, bites, or folds a branch or "leaf-clips" (tears a leaf while making sound to attract attention) in front of the desired playmate.

As a display to others, chimpanzees perform "leaf-pile pulling", where an individual walks backward while noisily pulling dry leaves with both hands and "leaf-pile pushing", a similar but less common behavior where the leaves are pushed forward instead.

In addition to the common behaviors described above, there are rare reports of social play using tools: subadults were once observed playing together with a blue duiker, and on one occasion an adolescent female used a monkey's tail (leftover from a kill) to tease a juvenile male.

During solitary play, chimpanzees push and rub stones, sticks, twigs, leaves, or food items to tickle themselves ("self-tickle"); play "blindman's bluff" (an individual drapes an object over the face and moves around); drape pieces of vegetation (liana, lichen) on their head or animal skins (baboon, bushbuck) on themselves; and repeatedly throw a stone some distance and get it back. There are also single observations of solitary tool play: once a young male tossed a round fruit into the air and tried to catch it several times (succeeding only once), and an infant used a stick to club an insect.

Chimpanzees treat objects or animals like infant conspecifics, a behavior called "doll play." They hold, cradle, carry, and take into their nest small pieces of vegetation (sticks, logs, woody vines and bark) in a way that resembles maternal behavior toward infants. Similarly, once a female groomed and carried a hyrax and slept with it at night in her nest. In a comparable behavior, two times an adolescent male used a branch in a way that it seemed to symbolize a playmate: he wrestled with the branch, and slapped and mounted it.

Chimpanzees exhibit tool play behaviors that seem related to adult tool use. Infants introduce twigs and grass stems into termite mounds and poke at other objects (e.g., mother's leg) or perform other actions with twigs that are similar to

those involved in termite fishing, sometimes during or after observing their mother termite fish. Infants use sticks to poke ant trails. Individuals show several tool play behaviors related with obtaining water. They insert long objects (such as twigs or grass blades) into water cavities and then suck them. They make a sponge by chewing leaves, and use it to absorb water or “extract” water from what seems imaginary tree holes. Finally, they fold leaves into cups or “leaf-spoons” to get water.

Bonobos

Bonobos exhibit two behaviors to solicit play. The first one is “play-start”, where an individual waves a small branch and runs with it as a signal to be chased by a potential playmate (any other player is later chased if gets and holds the branch). The second one is “leaf-clipping”, where an individual “leaf-clips” and holds the leaves in the mouth while watching the desired playmate.

A stick may function also as a play indicator: one player holds a stick while players wrestle or move without intending to get the stick and not directly playing with it, but if the stick falls, it is retrieved or replaced before reassuming play. Thus the function of the stick seems to be to signal that play is taking place.

Similarly to chimpanzees, bonobos also perform “tug-of-war” and “doll play”, the last one using red-tailed monkeys.

Orangutans

The following tool play behaviors have been reported for orangutans. “Play nests”, where individuals build nests during play with others but without using them for resting. “Snag riding”, where an individual pushes over a snag and rides on it as it drops, holding onto vegetation before it gets to the ground. “Doll play”, where a female makes a leaf bundle, which she treats like an infant, holding it during sleep. In addition, youngsters detach branches and drape them on themselves playfully.

Gorillas

There is only one report of tool play in gorillas: once an adult male used a long-stemmed flower to tickle an infant.

Capuchins

Two games involving tools are reported for white-faced capuchins. The first one is the “hair-passing game”, where one individual bites a tuft of hair from another individual who attempts to get it back. The second is the “toy game”, where one player places an object (stick, leaf, bark fragment, or inedible fruit) in the mouth, while the other tries to get it. Each game differs, but in both either the hair or the object is passed several times from one player to the other, mouth to mouth, until the hair is lost and the object cannot be used. In addition, in one occasion a young capuchin poked another individual with a dead branch he had detached from a tree.

Western Red Colobus

During social play, individuals brake and wave long leaves, sometimes hitting a player with them to stop this individual from getting leaves to use as weapons in the game. As an invitation to play, they manipulate vegetation fragments while looking at the potential playmate and once an individual used a piece of a termite nest to solicit play from a human observer.

Vervet Monkeys

A juvenile tossed and retrieved an empty half-coconut shell several times (Rindal et al. unpublished data).

Interspecies

Chimpanzees and baboons play together “tug-of-war” with vegetation.

Evidence from Free-Ranging Populations

Rhesus Macaques

“Doll-play” behavior was observed in a juvenile female whose mother had an infant: she treated a piece of coconut shell as if it were an infant (Gomez and Martin-Andrade 2005).

Evidence from Captivity

In addition to the wide variety of human objects that enculturated great apes used as tools in play, the following tool play behaviors have been reported for captive primates (Ramsey and McGrew 2005; Gomez and Martin-Andrade 2005; Shumaker et al. 2011; Alexander and Hines 2002; Gruber et al. 2010).

Chimpanzees

During social play chimpanzees throw several objects (including sticks and dirt) at playmates, brandish sticks, use sticks to club each other and employ objects to solicit play (including in “play-start”).

To start social play chimpanzees also use a “peekaboo”-like game, where an individual covers the head with a towel and extends the hands toward a potential play partner, sometimes placing a towel on the face of another individual. Once, a youngster spontaneously began to cover and uncover his face with bedclothes in a “peekaboo” game.

During solitary play chimpanzees balance and climb poles, drape a wide variety of objects on themselves, use elongated pieces of vegetation and nails to probe holes and crevices, use containers to obtain and carry water, play “blindman’s buff” by covering the face with a towel and walking on the ground or in a tree, and exhibit “doll play” behavior. In addition, they have been observed to poke free ranging chickens in a game.

Bonobos

During social play bonobos use different objects (e.g., sticks, branches, paper) to strike and poke other bonobos or humans and drag a variety of objects (including a playmate who holds the object being dragged). To solicit play bonobos hold a stick in the mouth and agitate it, aimed throw objects, or roll a container in front of a potential play partner.

During solitary play bonobos throw and drag various objects, place buckets on the head, play “blindman’s buff” by covering their faces with objects (e.g., paper, branches) and moving around, and sit on an object (e.g., blocks and

balls) pushing their bodies across the floor with their legs. There are also single observations of solitary tool play: one time a female employed a piece of grass to gather ants from the ground, and another female pretended to drink from a bottle without actually ingesting any liquid.

Orangutans

During social or solitary play, orangutans place different objects (fragments of vegetation, cloth, rope, chains, food, and paper) on the head or around the neck. Once, two adolescents played a game taking turns: one individual put a shirt over the partner’s eyes and charged and wrestle him. In exploration, individuals dig with sticks.

Gorillas

Gorillas use branches (and once a piece of straw) for “self-tickling” and cover themselves with many natural and artificial objects during play. In one occasion, an individual used aimed throw during play.

The use of objects as dolls (“doll play”) by female gorillas has been reported several times. They treat objects (such stones, pieces of cloth, balls, shoes, and dolls) in ways similar to how mothers treat their infants.

Gibbons

Apparently playing, one time an individual pointed and threw a banana peel at a conspecific.

Capuchins

There are single observations of tool play in capuchins: a male draped a cloth around his neck, an individual put a bucket on its head, and a pet capuchin employed cloth towels to entice a kitten in play.

Vervet Monkeys

Individuals treat a toy doll in ways similar to how female vervets interact with infants, including performing an inspection of the “anogenital” area of the doll.

Macaques

Tonkean macaques drag branches during play. On one occasion, a rhesus macaque wore cloth pieces

over the head and face during play. Once, playfully, a long tailed macaque spontaneously tossed a rubber ring back to a human.

Conclusion

Tools used by wild primates in play consist mostly of pieces of vegetation, although other natural (such as stones and animals and their products) and rarely artificial (stolen from humans) objects are also used. Captive primates have access to a wide variety of both artificial and natural objects to use as tools, including toys, as a result of enrichment programs. Enculturated great apes use an extensive diversity of objects as tools during play with conspecifics or other species including humans. These apes play with toys in ways that are comparable to how human children play (e.g., they feed, dress, and hairbrush dolls and pretend to eat and drink from empty bowls and cups).

Many of the tool play behaviors exhibited by primates both in the wild and in captivity are cognitively complex. These include imaginary or symbolic (pretense), communication (signals), and those that resemble subsistence tool use (such as termite fishing). Several tool play behaviors are present both in the wild and in captivity in the same species, for example “play-start”, “blindman’s bluff”, and “doll play”. Furthermore, some tool play behaviors are exhibited by all great apes, for example, “doll play”.

In order to unequivocally distinguish tool play from object play, it is essential to be able to infer purposiveness in the behavior (Shumaker et al. 2011). However, this is not always easy to do, and it is likely that tool play is underreported in primates.

Touch

Dana R. Murphy
Department of Psychology, Nipissing University,
North Bay, ON, Canada

Introduction

As I approach the door to my office, I unzip the pouch where I keep the keys to my office and fumble for my keys. I am engaging in a haptic search where I will use only my sense of touch to locate the keys. Specifically, I am attempting to use the low-threshold mechanoreceptors (LTMRs) of the skin on the tip of my fingers to find the sharp metallic edge of my keys or the soft woven strap that is a part of the key chain holding the keys. In attempting to use only the sense of touch in searching for my keys, I am using the receptors found in the skin, the largest and most versatile organ of the human body which covers an area of approximately 2 m² (McGlone and Reilly 2010). Many times, the search is successful using only the receptors found in my skin. However, sometimes I cannot locate the important signs that distinguish the keys with my sense of touch alone and must resort to other sensory signals to find them (e.g., the sound the keys make as they jingle in the pocket

when I shake my bag, or the blue of the woven band of the keychain when I finally resort to a visual search when all other senses have failed me).

Discriminative Touch

The skin can be broken down into two very large areas including the glabrous, or hairless, skin of the palm and fingertips as well as certain parts of the face and the soles of the feet, and the hairy skin found throughout the rest of the body. The glabrous skin contains four different receptors that are characterized as low-threshold mechanoreceptors (LTMRs) that vary in terms of their adaptive responses to continuous stimulation and the size of their receptive fields – the area of skin to which the cell is responsive. In terms of their adaptive responses, LTMRs show a fast adaptation rate (fast adapting – FA cells) or slow adaptation rate (slow adapting – SA cells). FA cells, which include Meissner's corpuscles and Pacinian corpuscles, respond to deformation of the skin with an initial burst of action potentials that quickly subsides with continued exposure to the stimulus. When the stimulus is removed, there is another burst of action potentials. SA cells, which include Merkel's disks and Ruffini endings, respond with a continuous flow of action potentials during sustained contact with the stimulus. These action potentials subside once the stimulus is removed. In terms of the receptive fields of the LTMRs of the glabrous skin, those close to the surface of the skin (Meissner's corpuscles and Merkel's disks) are the most sensitive and have smaller receptive fields, while those cells deeper in the skin (Pacinian corpuscles and Ruffini endings) are less sensitive and have larger receptive fields. The fast adapting Meissner's corpuscles, with their small receptive fields, will be the most helpful in my haptic search for my keys.

The LTMRs are specialized receptors that effectively transduce mechanical forces contacting the skin into nerve signals that are then sent on to higher levels of the central nervous system. When exposed to vibrations, the LTMRs respond to different vibratory frequencies providing different types of information regarding the stimuli

encountered. The Pacinian corpuscles provide information about vibratory stimuli vibrating at frequencies between 40 Hz and 500 Hz and provide a sense of vibration (McGlone and Reilly 2010). McGlone and Reilly (2010) indicate that Meissner's corpuscles provide a sense of flutter from vibrations in the range between 2 Hz and 40 Hz while the Merckels disks provide a sense of pressure in the 0.4–2.0 Hz range. Finally, a buzzing sensation is provided by the Ruffini end organs from stimuli vibrating in the 100–500 Hz range (McGlone and Reilly 2010).

Abraira and Ginty (2013) indicate that the difference between the Type I (small receptive fields) and Type II (large receptive fields) SA cells is the regularity of their static-phase firing rates. SAI cells demonstrate a more irregular interspike interval than SAII receptors.

The LTMRs of the somatosensory system relay information regarding touch sensations to the brain via axons that synapse with second-order neurons in the dorsal root of the spinal cord or at the level of the brain stem in the dorsal column nuclei (Abraira and Ginty 2013). In the discriminative touch system described up to this point, the fibers running from the receptor cells to the spinal cord are highly myelinated A-beta fibers, whereas in the social touch system that will be discussed below, the fibers connecting the receptors to the spinal cord are lightly myelinated or unmyelinated C-fibers. Both A-beta fibers and C-fibers are believed to transmit noxious or painful stimuli to the spinal cord.

The receptor cells of the touch system are found mostly in the border region between the outer (epidermis) layer and the inner (dermis) layer of the skin. The number of receptors vary greatly depending upon the specific area of the body and the sensitivity of these areas of the skin also vary greatly depending upon the specific receptors found in that area and the types of connections these receptors make with the spinal cord and the brain.

The slowly adapting cells differ in the regularity of their firing rates. Specifically, SAI cells, with their location closer to the surface of the skin, have significantly smaller receptive fields and respond to stimulation with greater

irregularity in their inter-spike rate than found in SAII cells (Abraira and Ginty 2013). These cells respond to mechanical forces on the skin with a continuous, but somewhat irregular response throughout the stimulation (Abraira and Ginty 2013). They respond most effectively to “contact with corners, edges, and curvatures of objects” (Abraira and Ginty 2013, p. 621). They are also very sensitive to the position and velocity of stimuli due to their high spatial resolution (Abraira and Ginty 2013).

Social Touch

In addition to the receptive cells found in the glabrous skin, there are receptive cells found in the hairy skin. While there are many of the same receptor cells in the hairy skin as there are in the glabrous skin, there are also receptors that are found only in this type of skin. These cells have been called C-tactile (CT) receptive cells and connect to the spinal cord with unmyelinated C-fibers (McGlone et al. 2014). Evidence suggests that these receptors are responsible for the pleasant sensation associated with the touch of a loved one or the gentle caress of a caring individual (Ackerley, Saar, McGlone, and Wasling, 2014). Specifically, CT cells respond most effectively to slow stroking motions (in the range of 1–10 cm/s – Ackerley et al. 2014). Research indicates that these receptors respond most effectively to softer stimuli such as a soft brush compared to a harsh or rough surface such as that found on sandpaper (Essick et al. 2010).

The route of the CT receptors to the brain is also different from the route of the LTMRs relaying discriminative touch information. In particular, the unmyelinated C-fibers connecting these cells to the brain use a very slow conduction velocity compared to the myelinated fibers connecting the discriminative cells to the spinal cord. The CT fibers send their signals at a rate less than 2 m/s, whereas the discriminative fibers rates are closer to 60 m/s (Essick et al. 2010). In addition, they connect to different structures within the brain than the cells of the discriminative touch system. Using the mechanical stroke of a soft

brush on the forearm, an area known to have CT innervation and the palm, an area known to be devoid of CT innervation, and measuring brain activation using a PET scanner, McGlone et al. (2012) noticed different areas of activation depending on the types of receptor cells activated. Specifically, a slow stroke on the forearm, activating CT receptors in the forearm that send their signals along unmyelinated C-fibers, results in activity in the posterior insular cortex and the mid-anterior orbital-frontal cortex (OFC). These researchers indicate that stimulation of the palm, which does not have CT receptors, results in activation in the primary and secondary somatosensory cortices that process discriminative touch signals. While such stimulation on the palm is often considered pleasant, McGlone et al. attribute this experience of pleasure on stroking the palm to a learning process. Meanwhile, the stroking of the hairy skin in a way that stimulates the CT receptors causes an innate response in the limbic-related structures of the brain supporting the affective touch hypothesis that “the role of the CT system is to promote emotional, hormonal, and behavioral responses during contextually appropriate intra- and interactive tactile behaviors, such as nurturing and grooming” (McGlone et al. 2012, p. 1787).

The CT system has been linked to the development of social bonds in infants and in the connection between infants and their mother and may develop even before birth (Casio et al. 2019). As the infant develops, touch communication continues to play an important role in the child’s social development. Mothers and their infants interact with each other by touch in 65% of their interactions with these interactions frequently resulting in immediate reductions in both behavioral and physiological reactions to stress (Casio et al. 2019). Such social touch likely plays an important role in the social bonding resulting in successful attachment (Casio et al. 2019). In addition, when this type of touch is missing (for example, when the mother is clinically depressed), its absence can lead to problems. Infants deprived of touch from their caregivers or who actively avoid

it may end up with sensory processing problems such as over sensitivity (Casio et al. 2019). The disordered development of autism may make children overly sensitive to this type of touch which they may perceive as unpleasant causing them to avoid it and miss out on this important aspect of social bonding (Casio et al. 2019). The importance of touch continues throughout development with the connections between the peripheral touch receptors and the brain continuing to develop. Research indicates that the intensity of responses in the portions of the brain receiving the signals increases as the child develops from childhood into adulthood suggesting continued maturation of the social touch circuitry with continued brain development (Casio et al. 2019).

Conclusion

Clearly, touch is an important sensory modality providing important information to the individual about that person’s immediate surroundings. Touch can be used to identify objects when visual and other cues are not available and can aid in the process of object identification when other cues are not sufficient. Social touch plays an important role in human bonding and the development of social skills and human affiliation. The social touch system also appears to be different from discriminative touch with receptor cells found only in hairy skin, with the target of these cells being in different structures within the brain (McGlone et al. 2012). Research is currently underway to fully understand the importance of touch and how it might influence all aspects of life. We can look forward to these important discoveries so that we can better understand our sense of touch and the important information it gives us.

Definition

An overreliance on experimental methods in psychology comes with its problems of low context sensitivity, ecological invalidity, and limited scope of study. A move towards interdisciplinarity and methodological pluralism, along with an increased attention to the cultural context of behavior, can give greater validity to its findings, making psychology a more robust science.

Introduction

Gordon W. Allport, in his Presidential address at the 47th Annual Meeting of the American Psychological Association (1939), discussed the results of a survey they had conducted. It showed an increasingly empirical, mechanistic, quantitative, and analytic focus in the field of psychology. He warned against a “slavish subservience” to such a paradigm, pointing out how as a science, psychology, and its researchers ought to also be *rational, qualitative, idiographic*, and even *non-operational* (Allport 1940). Over the years, many researchers have pointed out this narrowness of the experimental methodology, including pioneers in the field such as Solomon Asch, Paul Rozin, Egon Brunswik, Michael Cole, and Ulric Neisser. The father of experimental psychology, Wilhelm Wundt, himself expressed his concerns about the inadequacy of the methods of experimental testing (Cole n.d.). However, a central part of psychology still remains primarily occupied by the experimental paradigm, dictating a quantitative tradition of collecting and interpreting data (Smith et al. 1995).

A major pitfall of such an experimental paradigm is the fact that it takes the human mind outside of its sociocultural environment. Jerome Bruner vociferously stressed upon the importance of culture in our psychological processes (Mattingly et al. 2008). Culture is intimately and inextricably linked with the way we think, feel, process information, interact, make decisions, and behave. Most psychological processes depend on

prior, culturally organized experiences, which differ greatly between societies. However, this relationship gets lost in the current state of psychological methods, which are based on carefully controlled experiments within the laboratory.

A Historical Unity

Psychology and Anthropology: An Important Relationship

Psychology and anthropology have seen some good days of conversation and interaction. Researchers from both the disciplines worked closely together for many years and the fields yielded much influence over each other. Psychologists like Wilhelm Wundt had, among his students, eminent future anthropologists like Franz Boas and Bronislaw Malinowski. Works of Sigmund Freud and his disciple Carl G. Jung was used by anthropologist Bronislaw Malinowski who, via ethnographic data, challenged the universality of Freud's formulation of the Oedipus complex (Bock 1988). Margaret Mead was influenced by Freud's ideas and used material from the Manus Islanders to amend his findings. Anthropologist and linguist, Edward Sapir (known for his linguistic relativity hypothesis) led a course on "The Psychology of Culture" at the University of Chicago (Mattingly et al. 2008). Researchers from both fields were also known to engage in substantial collaborations with each other. Psychologist Jerome Bruner worked in intense collaboration with researchers like Clifford Geertz, Claude Levi-Strauss, and Lev Vygotsky, for multiple years. Bruner taught at both departments of psychology and social relations increasingly attuned to the contributions that anthropological studies were capable of making in psychology. Michael Cole, working on numerical cognition, collaborated with anthropologists to demonstrate the impact of language in symbolization and the importance of culture in cognition (Cole 1967). These collaborations led to an insistence upon a meaning-centered approach in psychology, opposing the reductionist framework of an experiment-only paradigm. An interpretive framework was stressed upon, which turned to

be fundamental in the cognitive revolution of the 1950s (Mattingly et al. 2008).

Cognitive Science

Cognitive science arose as an interdisciplinary field, doing a scientific study of the mind and its processes. One of its great achievements lay in the integration of insights from linguistics, philosophy, anthropology, psychology, neuroscience, and artificial intelligence. This was followed by the emergence of cognitive anthropology in the 1950s, which embraced the idea of culture and understood its implications for mental processes. Cognitive anthropology, like many subfields of cognitive science, studied various theories on the representation of meaning and mental models. With collaboration between anthropologists and psychologists booming, a variety of formal and computational methods for analyzing and representing knowledge were also developed (Bender et al. 2010). However, methodological differences between the fields began to become salient, following a division of labor in the research questions: psychologists started studying *how* people think and anthropologists focused on the *what* (D'Andrade 1981). This led to an unprecedented dissociation of the two disciplines, each establishing themselves as unrelated departments. Eventually, the disciplines grew considerably divorced from each other's insights and developed a distaste for each other's methods: anthropologists were turned off by cognitive psychology's focus on studying undergraduates within highly artificial lab situations, using tightly controlled experiments and ignoring social contexts and real-world relevance; cognitive psychologists started to perceive anthropology as a story-telling enterprise, lacking in experimental rigor and making claims without presenting supporting data (Bender et al. 2010).

A Theoretical Unity

Despite the division of labor, a complete separation of the questions of content (what) and processes (how) of the mind is not possible without losing out on meaningful aspects of human behavior. Given that we grow up, adapt to, and function within a sociocultural world, culture affects not

only *what* people think but *how* they think. Culture provides a common ground for both research programs, and thus, for both disciplines. However, where many anthropologists are deeply involved in the study of culture, contemporary psychologists tend to bypass the mention of culture at all in their studies.

Our social and cultural lives are crucial contributors in the organization of our cognitive processes, making the study of culture in cognition indispensable (Bender et al. 2010). Developmental processes such as autobiographical memory and theory of mind capacities, due to their dependence on cultural environments, vary considerably between societies (Astuti 2015; Mayer and Träuble 2015); studies in linguistic relativity show that languages influence thought, mental processes, and behaviors (Boroditsky 2001); cultural constructs of individualism and collectivism have shown well-documented effects on cognitive processes of perception, reasoning, categorization, and attribution (Kim and Markus 1999; Nisbett et al. 2001).

The Importance of Culture in Cognition

Humans are overwhelmingly submerged in a cultural environment; it stays with us throughout our developmental period right up till we die. No other species is so thoroughly cultural. And indeed, if our brains are organized by experience (including learning), and experience is organized by culture, it naturally follows that culture would be a crucial formative force in the cognitive processes (Bender et al. 2010). Following are two examples demonstrating the importance of taking culture into account, while studying and understanding cognition.

Theory of Mind Theory of mind (ToM) is described as an innate cognitive module by which humans attribute mental states – beliefs, intents, desires, emotions, knowledge, etc. – to oneself and others (Butterfill and Apperly 2013). It is understood to be a universal ability in humans, usually arising at the age of 4 (Huemer et al. 2018). Quite contrary to this, some cultures practice a doctrine, stipulating that it is not possible for any individual to know what is inside other

people's minds and it is morally wrong to do so. This is called the “opacity of mind” doctrine (Robbins and Rumsey 2008). Mayer and Träuble tested ToM capacities in children from Samoa, a culture practicing the opacity of mind doctrine. Using the popular false-belief task paradigm, they found Samoan children to spectacularly fail in comparison with German children (Mayer and Träuble 2015). The experimental results directly suggested that Samoan children lack in ToM capacities or show a developmental delay. However, taking the children's social and cultural contexts into account, much richer inferences can be drawn: (a) Samoan children choose to not ascribe mental states due to the opacity of mind doctrine; (b) “intention” as a concept is irrelevant in Samoa (it is literally impossible to say, “I didn't mean to”), which is what the false-belief task was based on; (c) the children might have been confused by the “easiness” of the task and peculiarity of experimental settings, and indeed one of the children tricked the task itself (Astuti 2015); and (d) receiving instructions from anyone but their parents is unfamiliar to the Samoan children so they stay quiet and thus, fail the task (Mayer and Träuble 2015). Thus, it can be argued that an attention to the cultural environment can not only help in designing better experiments but also in better understanding the mental processes itself.

Visual Information Processing Studies of attention allocation and visual processing in cognitive science are heavily focused on understanding the underlying mechanisms, in an endeavor to find general regularities, if not laws, of visual perception. Egon Brunswik demonstrated the importance of *context* in studying visual processes, such as size perception (Brunswik 1956). More recent studies in visual perception have shown considerable differences between populations, which can be attributed to their cultural backgrounds. A study by Boduroglu, Shah, and Nisbett attempted to study attention allocation by using simple visual change detection tasks (Boduroglu et al. 2009). When shown changing groups of figures, American participants were quick at detecting changes at the center of the

field, whereas East Asian participants were significantly slower. However, the American participants were poorer at detecting changes happening on the periphery, while East Asian were considerably quicker. In such a case of varied results on the same task, culture can be an important explanatory variable: (a) East Asian participants are part of predominantly “collectivistic” cultures, which have complex, interdependent social networks, demanding more holistic cognitive styles; (b) holistic cognitive styles determine a wider focus – with great attention to one’s field and surroundings – explaining their performance in the visual change detection task; and (c) Americans come from social worlds whose ideologies emphasize individuality and independence, leading way to a narrower focus and attention to central objects. Indeed, multiple studies using various tasks have corroborated these findings (Chua et al. 2005; Nisbett and Masuda 2003), indicating a robust influence of culture in visual information processing.

Other examples of psychological and cognitive processes where culture has been seen to exert significant influence include, but are not limited to, attribution (the case of fundamental attribution error; Krull et al. 1999), fairness judgments (Henrich et al. 2005), object categorization (Nisbett and Masuda 2003), sense of morality (Baumard 2016), and even intelligence-testing (Cole n.d.). A complete understanding of human behavior indeed requires an attention to culture and context, along with the study of underlying mechanisms. Geertz called this a “thick description” of a behavior, which takes into account the cultural structures within which behaviors are produced, perceived, and interpreted (Geertz 1973).

A Methodological Disunity

Despite a historical and a theoretical unity, there is no question that psychology and anthropology have moved apart considerably as disciplines, with a major decrease in collaborations and interest towards each other’s findings. A primary reason for such a dissociation can be said to be the methodological differences between the fields. While anthropology studies human behavior

using naturalistic methods like ethnographic fieldwork, participant observation, unstructured and semi-structured interviews, etc. (Bernard 1994); psychology places a major emphasis on quantitative, experimental, and controlled studies in laboratory settings, in order to provide robust predictions (Howitt and Cramer 2007). However, in its urge to be seen as an advanced science, psychology has developed an overreliance on the experimental method, bypassing crucial steps of scientific investigation (Fish 2000). In any natural science study, from physics to biology and even ethology, a general logic of steps is usually followed: systematic observation of phenomena of interest; use of logic and convergent evidence to elaborate that understanding; and choosing investigative methods *in accordance with* the problem/object of study (Fish 2000; Rozin 2001). However, this is not reflected in the view of “science” in psychology, which tries to fit restrictive experimental paradigms and statistical analyses to all objects and phenomena of study, rather than the other way round. In this, they also tend to do away with naturalistic observations and push away anything less-experimental to the realm of less-scientific (Rozin 2001).

Shortcomings of Experimental Methods

Lab-based experiments give researchers the desired control to be able to find robust causal relationships (known as internal validity), provide relevant supporting data, and enhance replicability for verification (Roe and Just 2009). Experimental psychology has long built upon this by expanding procedures, devising new designs and evaluations, but without questioning the underlying framework (Brunswik 1956). The designing of experiments, given the constraints of the lab, and an ignorance of the real-life context of behaviors, has led to serious shortcomings:

Context Impoverishment Behaviors are adapted to specific environments for optimality and derive much of their meaning and function in view of the contexts that they are performed in (cultural environments being one of the main ones). However, as Solomon Asch disapprovingly pointed out, there is a strong tendency in psychology to gain rigor *at the*

expense of context sensitivity (Rozin 2001). Experimental frameworks tend to provide an individual-centered specification of behaviors, stripping away important parts of the context as confounding variables. Despite the experimental control this provides, it leads to a poor understanding of the behavior itself. For example, a wink, when objectively defined, is “the twitching and rapid closing of an eye.” It is only within a given context that one can understand the relevance of said wink – a signal from one friend to another before pulling a prank on the teacher or a covert gesture signaling intimacy between two people standing in a group, etc. (Geertz 1973). Thus, context impoverished explanations not only lack in real-life relevance but also applicability. Moreover, this makes way for undermining the cross-cultural aspects of behaviors (see criticism on psychology as being heavily ethnocentric; Fish 2000).

Low Ecological Validity Ecological validity of an experiment determines the extent to which the experimental setting is representative of real-life context and thus the extent to which the findings can be generalized (Roe and Just 2009). Brunswik (1956) was one of the first to point out the lack of ecological validity in psychology experiments, using the case of perception research. He reproached the psychologist’s preoccupation with studying “narrow-spanning problems of artificially isolated proximal or peripheral technicalities of mediation, which are not representative of larger patterns of life” (Brunswik 1956). While designing experiments, it is important to maintain integrity of the real-life situations that one is trying to study, pay attention to the social and cultural contexts of one’s participants, and take into account the participants’ interpretation of the experimental situation (Neisser 1976). However, most contemporary psychology experiments do not fulfill these requirements of ecological validity. Examples include, playing ultimatum and dictator games with strangers; getting handed a sum of money like windfall, which one then has to divide or put in a common jar; doing a repetitive joint task with a computer; and looking at animated creatures on the screen for judgments of opacity, etc. The concerns extend not only to the

experimental contexts but also the nature of tasks, the stimuli, and instructions given to participants (Schmuckler 2001).

Limited Scope An insistence on studying behaviors in the lab severely limits the range of social and psychological phenomena that can be explored. For example, important social processes like marriage, kinship, friendship, rituals, traditional pedagogical practices, etc. cannot be meaningfully isolated and studied in the lab. This limits the range of processes that psychologists can aim to study and discourages the discovery of new phenomena and creativity. Paul Rozin referred to this as a “phenomenological narrowness” (Rozin 2001).

Moving Towards Methodological Pluralism and Interdisciplinarity

Experiments bring with them a major benefit of providing internal validity and establishing causality, but it does so at the cost of context orientation, ecological validity, and real-life applicability (Roe and Just 2009; Elmes et al. 2011; Smith et al. 1995). Discontent with psychology’s methodological narrowness has led to a slight move away towards real-world studies and an integration with other data collection methods like field experiments, diary studies (Smith et al. 1995), ethnographic approaches and action research, naturalistic observations, and case studies (Elmes et al. 2011). However, such approaches remain relatively scarce and greater efforts need to be made in order to adopt a multimodal approach and move towards interdisciplinarity. The case of human behavioral ecology and evolutionary psychology, two scientific disciplines invested in the study of human behavior, shows how this goal can be meaningfully achieved.

Multimodal Approaches

While lab experiments provide greater rigor in identifying causal relationships, doing experiments in the field, with minimal alterations of the context, can provide ecologically valid results. Developing research schemes by combining lab and field experiments can therefore provide both external and internal validity to findings (Roe and

Just 2009). List exemplified this approach in his study on gift exchange behavior, where he created one research context in the lab and the other in a sports-card market with only minimal alterations (List 2006). By broadening our methodological scope in this manner, the advantages of a “sterile” lab experiment can be combined with context-relevant field data to provide sharper and more convincing results. Additionally, other sources of evidence such as surveys, questionnaires, ethnographies, etc. can be used to provide convergent evidence to strengthen one’s case (Rozin 2001).

Interdisciplinary Collaborations

Psychologists can participate in collaborations with anthropologists and other social scientists, in order to gather relevant information about the cultural contexts. Knowing about the sociocultural environments of one’s study, as well culture-specific behavioral norms relevant to one’s population of interest, can allow researchers to design ecologically valid experiments and make appropriate interpretations from the collected data. For instance, in the case of Samoan children, as suggested by Rita Astuti, knowing about the opacity of mind doctrine and cultural norms of obedience can lead to designing better experiments with the appropriate instructions for the participants. Only then can one be certain that they are *really* studying these children’s Theory of Mind capacities (Astuti 2015; Mayer and Träuble 2015). Anthropologists can have great contributions in psychological studies by providing information on how the cognitive processes of interest are employed in natural environments, and thus, help decide what kinds of hypotheses and design would be relevant to understanding the underlying processes (Bloch 1991).

The Case of Human Behavioral Ecology and Evolutionary Psychology

Many behavioral characteristics that are of interest to psychologists and other behavioral scientists are adaptations that have been shaped by natural selection during the course of our evolutionary history. Evolutionary psychology and (EP) human behavioral ecology (HBE) are the two dominant fields of study that apply evolutionary approaches towards understanding human

behavior, both having arisen from the parent discipline, sociobiology. Where evolutionary psychologists primarily work with the assumption that psychological mechanisms are the main unit on which natural selection operates, HBE considers behavior itself to be the main unit of selection (Durrant and Ward 2015). Both these approaches are crucial, given that any proximate description of a behavior – including psychological mechanisms – cannot be complete without understanding the ultimate explanation – the adaptive value of the behavior within the environmental context (Cronk 1991).

Researchers in these fields stress upon the importance of ecological constraints and natural and social environments for explaining observed behaviors (Nettle et al. 2013). In view of these research goals, the methodological repertoire includes, laboratory experiments, naturalistic observations, ethnographic work, evolutionary modeling, and participant observation. Given this multi-method approach, these fields provide good examples of a scientific study of human behavior, both ecologically valid and sensitive to the context. This is especially true of HBE which often works within departments of anthropology.

The methodology of HBE includes a combination of naturalistic observations and hypothetico-deductive models. Hypothetico-deductive models are built to predict how measurable variations in the social and natural environment affect an individual’s behavior, further affecting the individual’s chances of survival and reproduction (Nettle et al. 2013). Such models are constructed by collecting empirical data from self-report descriptions and surveys, such as national censuses, regular surveys of members of a cohort, and one-off questionnaires (Nettle 2012), as well as interviews and archival research (Winterhalder and Smith 2000). This is followed by formulating testable hypotheses and testing them out using *quantitative* naturalistic observations (Winterhalder and Smith 2000). Such a combination of models and naturalistic observations not only makes the findings more valid but gives the field more methodological rigor, vitality, ecological validity, and broad scope (Nettle et al. 2013). This was demonstrated by Nettle in his study of the relation between parental investment

and socioeconomic factors. He carried out direct observation of parents and children's behavior in natural public spaces, to extend and increase the validity of the conclusions produced by the previous self-report-based studies (Nettle 2012).

Attending to the issue of culture, which is the primary context where all human behavior takes place (as discussed above), participant observation can be another important methodological tool for HBE (Winterhalder and Smith 2000). This method, more regularly used in cultural anthropology, understands *culture as the context* of behavior. It can be described as “a way to collect data in a natural setting by ethnographers, who not only observe but also take part in the common and uncommon activities of the people being studied” (Bernard and Gravlee 2014). Participant observation has added epistemic value for HBE because, in addition to quantitative data collected by naturalistic observations, it allows collection of qualitative data like narratives, audio recording of people telling folktales, videotapes of people making canoes, getting married, having an argument, etc. (Bernard 1994). As Bernard (1994) explains, “quantitative and qualitative data inform each other and produce insights and understanding in a way that cannot be duplicated by either approach alone. Whatever data collection method you choose, participant observation maximizes your chances for making valid statements.” For example, Schnegg claims that participant observation provides information about relationships between people as well as the context in which behavioral data collection took place (Bernard and Gravlee 2014). Interestingly, this is precisely what Nettle (2012) pointed out to be one of the weaknesses of his parental investment study: by making only naturalistic observations, he was not able to infer relationships among the observed individuals and their lives inside their homes, which could have provided important insights to the study.

Conclusion

Maurice Bloch rightly said, “the basis of cognitive science is a combination of different disciplines, each with a contribution to make, but with a single

aim” (Bloch 1991). Understanding human behavior and human lives is no easy task. And psychology is definitely not the only discipline invested in this pursuit. Trying to solve a problem of such complexity by a singular methodological framework can only lead to an incomplete understanding. This entry is not to propagate the view that experimental paradigms should be replaced. Instead, newer avenues for data collection must be explored, and the importance of anthropology and other social sciences in the fields of psychology must be restored.

Trade-Off Between Exploration and Exploitation

Thomas T. Hills

Department of Psychology, University of Warwick, Coventry, UK

You could be reading this or you could be writing that long overdue article. The tradeoff is a natural one and it is the foundation of one of the oldest problems in animal evolution: How should an organism choose between exploiting a resource or exploring to find new resources? This problem is known as the *exploration versus exploitation trade-off* (EvE) and it cuts across domains – in decision research, visual attention, animal foraging, memory search, and computer science, the same basic problem repeatedly surfaces.

The diversity of situations in which this trade-off arises has, in turn, led to a diversity of solutions. In reinforcement learning, rules that achieve appropriate learning rates have elements of exploration intermixed with longer periods of exploitation (Sutton and Barto 1998). Rules such as the *epsilon-greedy algorithm* involve a greedy exploitative component that always chooses options with the highest known payoffs intermixed with some small (epsilon) amount of random exploration. The random exploration prevents the search from being captured indefinitely in local maxima and thus allows the search process to move away from bad initial guesses and to update its predominant choice if the environment starts to change. A similar algorithm based on physical properties of materials in relation to temperature is called *simulated annealing*. Simulated annealing uses “high temperature” phases that allow exploratory search (long distance jumps) through large regions of the search space before “low-temperature” regimes are invoked to exploit local regions of the space (using smaller jump sizes) that were discovered during the high temperature phase (Kirkpatrick et al. 1983). Social insect swarms, such as those of many ants and honeybees, exhibit analogous phases of diffusive and focused search in response to changing

resource distributions (Deneubourg et al. 1986). Finally, both biological evolution and artificial genetic algorithms address the EvE trade-off via altering mutation rates appropriate for moving through the adaptive landscape in smaller and larger steps. In some cases, these mutation rates can be altered in response to environmental changes such as stress – a process called *evolvability* (Gallardo et al. 2007).

Behavioral ecologists have observed this EvE trade-off in animal foraging, in a behavioral strategy called *area-restricted search* (Hills et al. 2013). This search strategy focuses search for resources in rich locations and avoids poor locations. The strategy accomplishes this by using sharp turning angles nearby where other resources have been found in the past and giving up on locations, by turning less sharply, when no resources have been found recently. This process therefore requires memory, as opposed to other search strategies, like Lévy flights, which do not. The amount of evidence needed to modulate between sharp and shallow turning angles depends on multiple factors, but giving up on a location is rarely due to a thorough search. The sensitivity of a search follows directly from what the organism expects to find locally in comparison with its anticipated opportunity cost for looking elsewhere. The anticipated opportunity costs can derive from personal experience or natural selection.

One of the most prominent models of EvE assumes that animals forage in *patches* of resources and are adapted to search optimally in their natural environment by knowing when to leave one patch and move to another. Animals do this by matching the instantaneous rate of resource acquisition within a patch with the long-term expected rate of resource acquisition across all patches. The optimal solution is provided by the *marginal value theorem* (Charnov 1976), and it has been shown to be effective in predicting a wide range of foraging behaviors in animals (Stephens and Krebs 1986) as well as humans (Hills et al. 2012; Pirolli and Card 1999).

From an evolutionary perspective, the EvE tradeoff is likely to be one of the most important

selective forces in the evolution of cognition (Hills et al. 2015). Numerous biological and behavioral aspects of cognition appear to derive from mechanisms that initially evolved to help animals explore in space. For example, the way humans control their attention is both biologically and behaviorally similar to the way many other animals forage in space (Hills 2006). This tells us much about the mind as it suggests that the attentional aspects of cognition are principally a search process (Hills et al. 2010). Moreover, by looking at the evolutionary development of cognitive search capacities, such as the capacity for simulating future action, we begin to explore much deeper questions, such as the evolution of the self (Hills and Buttefill 2015).

Tradeoffs in Mate Selection

Laureon Watson and Kristine M. Kelly
Western Illinois University, Macomb, IL, USA

Synonyms

Mate preferences

Definition

The necessity for males and females to prioritize some qualities over others in potential mates in order to maximize reproductive success.

Introduction

A key factor in mate selection is differential parental investment offered by varying partners. Parental investment can be defined as the time and

resources devoted to raising one's offspring, thereby increasing the offspring's survival and reproductive success but limiting the parent's future reproductive activities (Trivers 1972). According to Trivers, there are sex differences in parental investment, especially in obligate levels of parental investment. In most species, females necessarily invest more in procreation than do males; female sex cells are larger and more metabolically costly, and females are responsible for internal gestation and lactation following birth. The sex whose typical parental investment is greatest will become a limiting resource for the opposite sex; thus, members of the lesser-investing sex will compete to breed with members of the higher investing sex, and members of the higher investing sex will be more selective of mating partners. While humans are included among those species in which reproduction comes at a greater cost to females than to males, human men typically invest a good deal of time and resources into their offspring, which makes them more selective in their mate choice as intention to invest increases.

Strategies for Optimal Reproductive Success

Both men and women have evolved strategies, guided by circumstantial cues, to optimize their investments in mating and child-rearing. In many species, the reproductive success of one sex is directly related to number of partners, but the other sex is limited in reproductive success by internal gestation and lactation. Males usually fall into the first category, females into the second; thus, women are a limited reproductive resource for men. This means that men must put more effort than women into intrasexual competition, or competition with members of the same sex for access to members of the opposite sex. Due to the sex differences in obligate parental investment, men stand to benefit reproductively from securing access to as many partners as possible (Buss 1989). The optimal mating strategy for men, then, is to devote a greater amount of energy to competition for mating access than to parental investment and to seek short-term relationships requiring little investment.

However, because women have fewer reproductive opportunities than men, and because

obtaining a greater number of mates does not create large reproductive gains for women, they should devote more time and energy to parental investment and seek long-term relationships in which their partners are willing and able to invest in offspring (Buss 1989). While short-term mating is more conducive to the optimal male strategy, both men and women engage in short-term mating. Women seeking a partner may use short-term mating to evaluate the quality of a potential long-term partner. Partnered women may also use short-term affairs as a means of obtaining better genes for their offspring from a highly attractive mate, while continuing to receive resources and investment from a long-term partner (Buss and Schmitt 1993). As levels of expected investment in relationship contexts increase, mate preferences and standards may change, and both women and men may be attracted to different qualities in short-term mates than in long-term partners (Gangestad and Simpson 2000), as will be discussed in more detail below.

Sex Differences in Mate Preferences

Research on mate preferences has tended to focus on a stark sex difference: men tend to value attractive mates more so than women, while women tend to value status and resources in mates more so than men (Buss 1989). In line with evolutionary theory, it is adaptive for individuals to be tuned into traits in potential mates that will best support successful production and survival of offspring. A man's value in reaching that goal may be more closely tied with his ability to offer resources to offspring, while a woman's value in doing so may be more related to her health and fertility (Buss 1989). Female fertility can be assessed by visual cues in appearance, which leads men to be more attuned to the physical attractiveness of potential mates. On the other hand, resource acquisition can be assessed by status and earning capacity, which creates in women a preference for these characteristics in potential mates (Symons 1979; Buss 1989).

Trade-offs in Mate Selection

Mate trade-offs can be understood in terms of economics: when given unlimited resources,

people spend freely on luxury items. However, when on a limited budget, people buy necessities first and may spend some leftover money on luxuries. The same principle applies to mate choices: individuals make different mating choices depending on the size of the “budget” at their disposal (Li et al. 2002). When describing an ideal mate, most individuals do not depict perfect 10 s; rather, they calibrate their desired partner traits to their own because this creates realistic mate standards (Campbell et al. 2001). Men desire at least a sufficient level of physical attractiveness in a mate, because women’s physical qualities can indicate their fertility status; although other qualities of women may have effects on child rearing, none of them are reproductively useful if she is not fertile. Likewise, because there is variation in men’s access to resources, and because access to resources affects offspring survival, women should require a minimum level of status or resource acquisition before they consider other traits in a potential mate (Li et al. 2002). Although a sex difference in preferences for physical attractiveness and resource acquisition exists, other traits, like personality and kindness, tend to be equally valued and prioritized by both sexes. Similarly, intelligence seems to be a necessity in a potential partner, as a sufficient amount of intelligence may be necessary for successful parenting (Li et al. 2002). However, the level of each of these characteristics that is considered “sufficient” may vary depending on relationship contexts.

Differences in Preferences Based on Mating Contexts

Strategies and mate standards may vary depending on the mating context and whether the union is intended to be short term or long term (Buss and Schmitt 1993). Both short- and long-term relationships have potential benefits and costs that vary differentially by sex. As previously discussed, men stand to benefit greatly from a series of short-term relationships with as many partners as possible. In short-term mating contexts, then, men should have lower standards for mate qualities. As explained by parental investment theory, women should be more selective of partners due to higher reproductive costs

for women than for men and because women are more likely than men to be the sole parent caring for offspring resulting from a short-term sexual relationship (Trivers 1972). As mating context commitment level decreases, both men and women desire higher levels of partner attractiveness, as good genes for offspring are the main benefit acquirable through short-term relationships (Buunk et al. 2002). However, in long-term relationships, characteristics indicating competence, cooperation, and good parental investment are more highly valued in potential partners (Fletcher et al. 2004).

Conclusion

Biological differences in males and females lead to differences in parenting requirements for men and women. Qualities that suggest good reproductive potential are found most attractive by prospective partners, but some of these qualities also vary between men and women, creating a sex difference in mate preferences. However, these preferences may shift according to the mating context and whether an individual is seeking a mate high in parental or genetic quality. As it is often not feasible to acquire a mate with high marks in both of these categories, men and women alike must make trade-offs in mate selection in order to maximize reproductive success.

[Dispositional theories](#)

Definition

Trait theories are the theories in personality psychology whose common denominator is treating traits as key elements in the description of personality. These include Allport’s theory, Cattell’s theory, Gray’s biopsychological theory of personality, Eysenck’s three-factor model, and the five-trait theory of McCrae and Costa. The integrative Big Five trait taxonomy is the most popular and most frequently used.

Introduction

While the representatives of trait theories do not share a common definition of a trait, they agree that it is a disposition to display behaviour in consistent patterns in various situations (Pervin and John 2001). Personality theorists understand traits in two possible ways: either as descriptive summaries or as internal causal properties of behaviours. The authors of the currently

predominant approach define traits as “dimensions of individual differences in tendencies to show consistent patterns of thoughts, feelings, and actions” (Costa and McCrae 1990, p. 23). This prehension includes not only behaviour but also thoughts and feelings. The third crucial term in the definition of traits, besides disposition and consistency, is the stability over time of a given person’s behaviour.

One field of research on personality traits is studying trait heritability. Metaanalyses have shown that the average effect of genetic contributions to individual differences in personality traits ranges from 30% to 50% (Plomin et al. 2008). The evidence for trait heritability is stronger for temperament-related traits (e.g., emotionality according to Buss and Plomin 1984).

Allport’s Theory

Gordon Allport (1937) defined traits as generalized personal tendencies which determine how humans behave in most of situations. This theory distinguishes between three types of traits: cardinal, central, and secondary dispositions. According to Allport, some traits may initiate behaviours. Allport’s theory makes two characteristic assertions with regard to traits. The first assertion is that traits are real entities derived from the nervous system. The second assertion amounts to the statement that apart from common traits there are also traits unique to each person. Simultaneously, Allport did not ignore the role of situation, claiming that traits do not have to be apparent in all situations.

Eysenck’s Theory

According to Hans Eysenck (1990), personality is hierarchically structured. Traits consist of groups of habits and combine into higher-order factors. Eysenck used factor analysis, a statistical method which allows to identify groups and subgroups of correlated behaviours or test items in order to discover the components of personality structure (Pervin and John 2001). By using this technique,

he was able to distinguish the three basic dimensions (so-called superfactors) of personality: (1) extraversion, (2) neuroticism, (3) psychoticism. Eysenck claimed that the individual differences in trait intensities are genetically and biologically determined and reflect differences in neurophysiological functioning. Eysenck’s theory suggests that traits are explanatory concepts. His assumption that the superfactors in a healthy human population are orthogonal (not correlated with one another) was questioned by Gray (1987), among others.

Cattell’s Theory

Raymond Cattell (1965) accounted for a greater number of traits in personality description than other trait theory proponents who used factor analysis. He distinguished surface traits, which can be studied with subjective methods, and source traits, which are the real expression of covariant behaviours and which can only be grasped using factor analysis techniques. To determine the structure of personality, Cattell used three types of observational data: L-data (life data), Q-data (questionnaire data) and T-data (test data). Cattell distinguished among cognitive-ability traits, temperament-stylistic traits, and dynamic traits. He eventually identified 20 personality traits.

The Big Five

The advocates of the Big Five model claim that the number of traits can be reduced to five. Though the names of these traits have not been standardized, the following traits are usually listed: (1) neuroticism (including “a tendency to experience dysphoric effect”), (2) extraversion (including “a preference of companionship and social simulation”), (3) openness to experience (including “a need for variety, novelty, and change”), (4) agreeableness (including “a willingness to defer to others during interpersonal conflict”), and (5) conscientiousness (including “strong sense of purpose and high aspiration level”) (McCrae and Costa Jr 1999, p. 143). The first stage of the personality research which led to

the identification of the five factors used a lexical approach (Goldberg 1990). It was assumed in this approach that there are colloquial names for the majority of universal and important personality traits, which are significant in contacts between people. The authors of the five-factor model of personality which explains the dimensions of the Big Five are Robert McCrae and Paul Costa (1999). They demonstrated that the Big Five structure can also be revealed based on questionnaire studies carried out in various cultural circles. It was found that there is a strong convergence between the results of both lexical and questionnaire studies (McCrae and Costa 1987). McCrae and Costa considered traits as fundamental, biologically determined tendencies. They also accounted for the fact that personality traits can be influenced externally (e.g., by psychoactive substances or traumatic factors) through the biological bases (McCrae and Costa 2008).

Many studies have shown that the Big Five traits are strongly affected by genetic and environmental factors. Both twin and molecular studies reveal genetic determinants of personality traits. The results of molecular analyses are less conclusive compared to twin studies. For instance, there is both evidence for and against a relationship between personality factors measured using the NEO-PI-R questionnaire and polymorphisms within the studied genes (e.g., the Serotonin Transporter Gene – 5-HTTLPR) (Ebstein et al. 2003). Indeed, the results of studies on the potential impact of specific gene polymorphisms on personality traits seem to indicate that individual genes do not have strong effects on the Big Five traits. Some authors (e.g., Bouchard and Loehlin 2001) interpret the genetic influences on personality from an evolutionary perspective. The proponents of the evolutionary approach suggest that some traits may have been more essential for survival than others.

Conclusion

While the representatives of trait theories were united in treating traits as key components of

personality, many differences can be found as well. These differences mostly involve the methods used to determine personality traits and the postulated number of these traits. For instance, Allport employed the lexical approach, while Cattell and Eysenck developed their theories using the methods of factor analysis. McCrae and Costa, in turn, referred to both lexical studies and factor analyses. Currently, some of the most popular models in personality psychology are personality models based on the five-factors idea. Objections to trait theories mostly concern their status as descriptive theories, as the traits do not explain human behaviour.

Definition

The transfer of sperm through a physically inflicted wound (wound = trauma [Greek]).

Introduction

Traumatic insemination (TI) is a special form of traumatic mating (TM) that refers to cases where routinely “the partner’s intra- or extragenital integument is wounded by specialized devices in the direct context of copulation” (Lange et al. 2013).

This explanation excludes accidental cases of copulatory wounding, which perhaps can happen in any group of animals with internal fertilization. Other forms of TM refer to cases where only seminal fluid, but no sperm, is transferred through the wound, or traumatic penetration with neither sperm nor seminal fluid transferred (Lange et al. 2013).

Far from being a bizarre, even aberrant, behavior, recent systematic reviews (Lange et al. 2013; Tatarnic et al. 2014; Reinhardt et al. 2014) identified both TM and TI as being widespread in the animal kingdom. For example, TM is currently known to have evolved independently approximately 50 times.

Species vary in whether TM occurs inside or outside the genital tract. In some species the trauma is inflicted at a very specific location on the female body; in others, mainly concerning species where only seminal fluids are delivered through a wound, the location is not fixed, and TM can happen anywhere on the female body (Lange et al. 2014). The location the male uses to inject seminal substances might be related to neuronal manipulation (Lange et al. 2014), to bypass the female reproductive tract or to deliver physiologically active substances closer to their target site. Alternatively, the location of trauma infliction may be the result of selection on males, for example, if female responses to sperm have made it advantageous for males to inject sperm at specific sites only.

The trauma is inflicted by a variety of structures, differing in developmental origin, including penis spines, specialized stylet structures, or

spermatophores. In several species, even the chemical lysis of the female skin has been observed, through which sperms are subsequently delivered (Lange et al. 2013). The frequent analogous occurrence of TI strongly suggests a benefit to at least one of the involved parties.

Benefits of TI to Males

TI and TM have generally been discussed in the framework of sexual conflict. It is assumed that males performing TI benefit either by an advantage over other males or by gaining control over aspects of the female reproductive output (Lange et al. 2013; Tatarnic et al. 2014; Reinhardt et al. 2014). It has been suggested that sexual conflict is particularly strong in hermaphrodites because here any intersexual conflict would simultaneously be intragenomic. No direct test of this idea is available, but evolutionary transitions toward TM occurred seven times more often among hermaphrodites than in separate-sex species, relative to their species number (Lange et al. 2013).

TI by males may be a side effect of other male characters under selection, or it may be directly under selection, likely originating from benefits from an ancestral event of accidental copulatory wounding.

Support for the scenario that TI is a side effect of other functions under selection comes from cases where neither sperm nor ejaculate substances are transferred through the wound. The benefit to males would be to tightly anchor their copulatory organs within the reproductive tract of females. Hence, the regular mating traumata result from selection for anchorage, not for wounding itself.

Direct selection for TI may occur in two cases (Lange et al. 2013, for details). First, the adaptive harm hypothesis proposes that TI temporarily increases the female’s output of eggs that are fertilized by the traumatically inseminating male. This hypothesis is based on the concept of terminal investment. The wound generated during TI signals to the female the approaching death and so may lead to a terminal allocation of all remaining resources into reproduction, at the cost of somatic

maintenance. While theoretically plausible, the available empirical evidence, mainly tested in insects, is not supportive.

Second, TI may increase a male's paternity share without acting on the partner's fecundity. This may arise when, by TI, sperm circumvents parts of the hostile female reproductive tract, for example, by being placed closer to the site of fertilization, or if the trauma itself alters the sperm uptake by the respective male. In both cases, males performing TI have an advantage over normally mating males. To test these two scenarios competitively, species would be required that show both types of mating simultaneously – an exceedingly rare case (Reinhardt et al. 2014).

Costs of, and Female Response to, TI

During TI several potentially costly processes occur in the female. Blood loss may weaken the female; the wound may also represent an entry port for microbes, including sexually transmitted diseases, and for molecules in ejaculate fluid. The wound as well as the entry of nonself particles will activate immune and repair cascades which are costly. Several attempts to quantify the costs to females have been made (Reinhardt et al. 2014). However, as TI regularly results in wounds, females are expected to adapt rapidly. Consequently, costs to females measured by observation represent those in the presence of female defense structures and may be low. In fact, current costs to females may only be marginally higher in species with than without TI (Reinhardt et al. 2014). In some insect systems, however, costs can be measured by experimentally circumventing the female defense system. Experimental TI mimicking the ancestral situation in which females have no defense system yet shows costs in the order of 25 % in terms of female lifespan or fecundity.

Following basic coevolutionary theory, females can respond by three different ways to TI, by avoidance, resistance, or tolerance. As females cannot entirely avoid mating, most emphasis has been placed on female resistance

(Holland and Rice 1999). Female resistance reduces the costs to females and consequently the effectiveness of TI. The reduced male success then leads to selection on exaggerated TI traits in males. Recently, the notion of tolerance in sexual conflict has been borrowed from plant-herbivore and host-parasite coevolution (Michels et al. 2015). Under tolerance, females cope with the damage incurred during TI, for example, by sophisticated wound repair but without generating a disadvantage to the male. The consequent lack of selection on males may lead to a stop of coevolution of that particular trait pair. Consequently, other conflict-causing traits in males may be positively selected from the genome and so generate greater trait diversity by tolerance than by resistance (which leads to exaggeration, not diversity).

Benefits of TI to Females

Theoretically, females may benefit from TI if the wounding costs are outweighed by other costs. The female's own immunization, superior performance of sons of traumatically inseminating males, or superior defense by daughters of traumatically inseminating males have been suggested as potential benefits to females. No empirical evidence is available to test these ideas, and several theoretical points also argue against them. For example, indirect benefits are usually small and the quality of sons may be under a trade-off with the quality of daughters.

Evolutionary Trends in TI

Four major evolutionary trends of TI have been identified (Lange et al. 2013; Reinhardt et al. 2014):

- (i) With evolutionary time, the complexity of the organs involved in TI increases in both male and female genitalia. Prime examples are dart-shooting mollusks.
- (ii) In other groups, males evolve simple, needle-like intromittent organs, such as in the Strepsiptera or bedbugs.

- (iii) Thickened or sclerotized tissue evolves at the site of wounding, particularly impressively shown for females across a range of bruchid beetles.
- (iv) The female strategy of tolerance to TI may lead to female defense structures that are open for the male to enter and, therefore, do not represent a trauma anymore.

Traumatic Sexual Intercourse in Humans

Consensual sexual intercourse in humans regularly leads to mucus abrasions or skin lesions; 10% to >50% of women examined showed such symptoms (see references in Reinhardt et al. 2014). As such, sex causes wounds on a regular basis. Why it regularly occurs and possible variation between women, or men, are not clear. Some evidence suggests that sexually inexperienced women may be especially prone to injury (e.g., Tchonzou and Chichom-Mefire 2015). Case studies of genital injuries reported in the medical literature refer to penovaginal disproportion, excessive force, or unusual behavior at coitus (Eke 2002). In whatever way these terms will be defined, it remains unknown whether they are generally associated with traumata during sexual intercourse or remain individual cases. However, such questions are not out of reach of research.

Forensic studies revealed that nonconsensual sex sometimes results in more female genital injuries compared to consensual sex (see references in Reinhardt et al. 2014). However, a standard classification of genital injury after sexual intercourse was developed only recently (Kelly et al. 2013), and it remains unclear whether the differences between studies are real, methodological, or devoted to differences between investigated women. For example, many victims of non-consensual sexual intercourse are outside of reproductive age and may, therefore, differ in responses to injury.

In humans, there is evidence of healing of genital wounds as 36 h after injury fewer wounds were reported than 0–24 h after injury (see references in Reinhardt et al. 2014). If traumata during sexual intercourse occurred regularly in humankind's

past, or in the past of their primate relatives, it is not unlikely that selection acted on rapid wound healing in the genital tract. However, no information is available to compare the speed and efficiency of wound healing inside and outside the genital tract.

Open Questions and Future Research

Most earlier reviews have concluded that TI is understudied and underreported. Arguments that TI is even more frequent than current data suggest include the notion that copulation itself evolved frequently and copulatory organs evolved from many different developmental structures. The resulting evolutionary volatility will frequently generate events of accidental copulatory woundings, which is a likely precursor to TI. Particularly striking in this respect is the frequent and independent evolution of male intromittent organs with spines, hooking or piercing devices, ranging from insects and nematodes to mammals.

In the bedbug family (Cimicidae), two species exist where males traumatically inseminate other males. Since such behavior cannot serve a direct reproductive advantage, a study of these two species might reveal additional functions of TI.

Finally, resurrecting the ancestral state of TI, where females have no defense structure, and then measuring the costs and benefits of TI may be useful for further species. Particularly little is also known about variation across different populations of a species, and nothing on intraindividual differences in wounding or being wounded (Reinhardt et al. 2014).

A special challenge to both the definition and the methods to study TI is posed by the study by Mouginot et al. (2015). These authors show that males impose a dysfunctionalization of the female genitalia after they have mated, that it functions to prevent female remating, and that such behavior may be frequent in spiders. This behavior, for which the authors suggested the term female genital mutilation, is not a case of TI but falls into the realm of TM. While it is clear that it increases a male's paternity share without

acting on female fecundity, other driving evolutionary forces are worth studying.

Conclusion

It is clear that traumatic insemination is a common phenomenon in the animal world. It is one of similar processes subsumed under traumatic mating, which also occurs in humans. Both, male benefits of TI as well as female defense responses warrant further study to understand both evolutionary processes as well as obscure facts related to human reproductive health.

Tribalism

Alexander Mackiel

Department of Psychology, State University of New York, New Paltz, NY, USA

Synonyms

In-group–out-group dynamics; Intergroup conflict; Parochial altruism

Definition

Tribalism is a word that contains a variety of phenomena that relate to loyalty to and favoring of groups to which one belongs. These phenomena include a number of cognitive and behavioral manifestations of that adherence, which can be seen at every level of human social life from the dyadic interaction to the sociopolitical and institutional structure of a nation.

Introduction

All individuals are embedded within a set of concentric social circles. The first circle contains their immediate family members and close friends. Surrounding that is a larger circle of more distant family members and friends, as well as acquaintances. Around that circle is an even larger circle of strangers that belong to the same community and visit the same groups and locations. But this is just the beginning. People also have affiliations such as group membership to a nation, political group, social club, sports team, religion, that create connections between individuals within these different circles as well as between still larger circles that span national boundaries. Therefore,

the human social environment is complex and multifaceted. It contains intersecting and often contrasting loyalties that are at least partly hierarchically arranged. However, one thing is clear from decades of research into how we make groups and cognitively represent them within our social worlds: We tend to prioritize and favor individuals that are closer to us, a tendency known as tribalism (Greene 2013).

This tribal tendency is evident in a wide variety of human behaviors and cognitive mechanisms that works towards the function of cooperating with, and expressing loyalty to one's in-group (i.e., within-group cooperation) or expressing disagreement and hostility toward out-groups (i.e., between-group conflict) (Balliet et al. 2014; Clark et al. 2019; Tajfel 1982). Tribal tendencies manifest in various areas of human social life including politics and warfare, ethnic and racial discrimination, morality, and sports teams. They include in-group favoritism (Balliet et al. 2014; Clark et al. 2019), discrimination and hostility towards out-groups (Balliet et al. 2014; Tajfel and Turner 1979), biased moral reasoning (Ditto et al. 2009; Clark et al. 2019), and ideologically motivated reasoning (Ditto et al. 2018; Kahan 2013). Many of these tribal tendencies are likely rooted in evolutionary theory. Exploring the evolutionary logic of the socio-ecological conditions that make tribal tendencies favorable along with comparative evidence from apes helps to elucidate the forms and functions of human tribalism.

The Origins of Tribalism

The starting point for the evolutionary argument for tribalism is fairly straightforward: Humans almost certainly evolved in contexts where either (but likely both) within-group cooperation and between-group competition (aka intergroup competition) occurred (Tooby et al. 2006; Tooby and Cosmides 2010; Wrangham 1999). In both cases, individuals are pressured for two different but related processes, toward tribalism. In the case of within-group cooperation, groups that are more cohesive, coordinated, and composed of individuals who are committed to shared goals, are more likely to be stronger competitors in intergroup

competition (Tooby and Cosmides 2010). This is especially the case when in-group members penalize free-riding behavior and reward loyalty, which is often the case (Clark et al. 2019). In the case of intergroup competition, individuals who can better identify in-group versus out-group members benefit from intergroup competition (Greene 2013).

Additionally, in order for cooperative groups to be efficient, groups must protect themselves from the exploitation of free riders within the group and from enemies between groups (Tooby et al. 2006). Rewarding cooperators and punishing defectors is one way in which within-group cooperation is maintained. And the ability to distinguish Us from Them, and the tendency to favor Us over Them, is how cooperative groups protect themselves from exploitation from external threats (Greene 2013). Anthropologist Donald Brown identified in-group bias and ethnocentrism as universal in his survey of multiple cultures, which suggests the ubiquity of the Us versus Them mentality (Brown 1991).

The Evolution of Intergroup Conflict

Researchers applying an evolutionary lens to human behavior have argued that tribalism is based on our coalitional psychology – that is, our proclivity to create and support our coalition against other competing coalitions (Tooby and Cosmides 2010; Wrangham 1999). These coalitions can potentially take the form of any kind of group-based formation such as identity-based coalitions (e.g., race and gender), political, and war coalitions, and institutional coalitions. (Pietraszewski et al. 2015; Tooby and Cosmides 2010). Tooby and Cosmides (2010) describe how humans have evolved to join and create alliances and coalitions from the demands of conflict since individuals learned that they could increase their formidability by pooling their strength and formidability into groups.

Perhaps the most obvious implication of tribalism is intergroup conflict and aggression, which reaches its apotheosis in large-scale warfare. While the frequencies of wars have been in decline, war has been a common occurrence

throughout human history (Pinker 2011). Some scholars have taken the ubiquity of wars throughout human history and across time frames, cultural arrangements, forms of government, and demographic factors, to be evidence of war having some evolutionary basis (Wrangham 1999; Wrangham and Glowacki 2012).

The definition of “war” that is being used in this entry is given by Wrangham and Glowacki (2012) as “relationships in which coalition of members of a group seek to inflict bodily harm on one or more members of another group” (p. 8). Therefore, “war” is used interchangeably with “intergroup violence,” and “coalitionary killing.” War-like behavior can be found in chimpanzee intergroup aggression, which has a similar pattern to human war raids (Wrangham 1999). These similar patterns of human and chimpanzee intergroup conflict have led many researchers to study evolutionary parallels between these two species (Wrangham 1999; Wrangham and Glowacki 2012). For example, in both chimpanzees and humans, violence between members of the same species is often coalitionary, where members of the species (usually males) band together and engage in intergroup conflict (Wrangham 1999). The capacity to coalesce into coalitions is a necessary condition for intergroup conflict and war-like behavior. Lethal aggression in most other animals is usually dyadic rather than coalitionary (Wrangham 1999).

Wolves are one of the few non-primate species that engage in coalitionary killing, where there are relatively high rates of intraspecific killings mostly as a consequence of territoriality when rival groups meet at the edges of their territories (Wrangham 1999). Similarly, chimpanzee male groups defend their territories and when members of other groups encroach on their territory engage in hostile aggressive displays and behaviors, which can escalate into fighting and often killing (Wrangham 1999). Interestingly, research has shown that the rates of death from intergroup aggression in chimpanzees is similar to the rates of death in human intergroup aggression in small-scale societies, further adding support to the potential shared evolutionary origins of human and chimpanzee coalitionary aggression (Wrangham et al. 2006).

It is worth keeping in mind, however, that no single evolutionary pathway, or set of psychological adaptations is likely to account for the evolution of intergroup aggression. The evolution of something as complex as intergroup aggression is dependent on a multitude of factors including psychological processes, but also cultural, demographic, and ecological factors (Wilson and Glowacki 2017).

Additionally, the similarities between chimpanzee and human intergroup aggression are going to be limited to the type of human societies that better approximate conditions of chimpanzee societies, such as nonstate, hunter-gatherer groups lacking centralized political control and having independence from other societies (Wrangham and Glowacki 2012). But to fully acknowledge the breadth of human tribalism, it is important to take into account its evolutionary origins, starting from its rudiments we see in our close relatives, the Great Apes. Chimpanzees are mainly being discussed here because, while bonobos and chimpanzees are equally related to humans, evidence indicates that bonobos are in many ways the odd-one out, the one that is most derived compared to the common ancestor of chimpanzees, humans, and bonobos (Muller et al. 2017).

Intergroup Conflict in Humans and Chimpanzees

There is ample evidence that chimpanzees distinguish between in-groups and out-groups, and engage in intergroup conflict (Wilson and Glowacki 2017). Wilson and Glowacki (2017) describe a set of similarities between chimpanzees and humans that have a strong influence on their patterns of intergroup aggression and likely are key features for tribalism more broadly: (1) fission-fusion societies, (2) intergroup hostility, (3) male coalitions, (4) territorial behavior, and (5) coalitionary killings. Wilson and Glowacki (2017) also address striking differences between humans and chimpanzees that likely have had an effect on their development of intergroup aggression: (1) weapons, (2) the types of benefits gained by aggressors, (3) multilevel societies, and (4) language.

Humans likely differ in tribalistic tendencies from chimpanzees because unlike chimpanzee societies, human forager societies possess multiple distinct levels of social organization that form overlapping loyalties and affiliations for individuals. For example, individuals belong to families, collections of multiple families known as bands, and collections of bands that constitute ethnolinguistic groups. Of course in modern developed societies, there are even more layers, such as the nation, the ethnic/race, the cross-national religion, the continent, all of which provide different ways in which humans can and do draw circles around “Us” and exclude “Them.”

The most common form of coalitionary killing is the ambush also known as the lethal raid, which also results in the most deaths from warfare in forager societies (Gat 1999; Wrangham 1999). It is an unusual form of aggression compared to the rest of the animal kingdom because it is proactive rather than reactive and is usually unprovoked (Wrangham 1999). It involves small groups of males getting together and silently and quickly invading enemy territory to attack and then swiftly leave minimizing the potential for danger.

Wrangham (1999) highlights group territoriality and a fission-fusion system along with an asymmetry in power between groups, as being features that favor an evolved behavior of lethal intergroup killing, known as the imbalance-of-power hypothesis. Group territoriality limits access to resources and therefore favors behavior that leads to dominating neighboring groups and a fission-fusion system allows individuals to assess when attack is most likely to be successful (i.e., when the power asymmetry is in favor of the aggressors) (Wrangham 1999; Wrangham and Glowacki 2012). Doing so, increases reproductive and survival benefits to the successors as they now have greater access to food and potentially mates (Wilson and Glowacki 2017). Wrangham and Glowacki (2012) assess warfare among nomadic hunter-gatherers and compare them to the chimpanzee model expectations, which are hostility to other groups, attacking out-group members and doing so when safe, and benefitting from such attacks. They find many consistencies between human intergroup conflict and the chimpanzee model, suggesting the

model provides an accurate foundation for understanding the biological and cultural evolution of war (Wrangham and Glowacki 2012).

Tribalism in Social Perception: In-Groups Versus Out-Groups

The degree of human tribalism present in human nature is evidenced by how early on we begin to slice our social worlds based on morally relevant behaviors. In an experiment of social evaluation of behavior, researchers demonstrated that long before infants can walk or talk, they are making value judgments about appealing and aversive individuals (Hamlin et al. 2007). The researchers show that 6-month-old infants prefer helping individuals over hindering individuals, prefer helping individuals over neutral individuals, and prefer neutral individuals over hindering individuals.

They show this with the use of geometric shapes with googly eyes where a red circle attempts to climb a hill and is either pushed up the hill by a nice triangle (helper) or pushed down the hill by a mean square (hinderer). Importantly, in one of their experiments, they run the same set up but without the eyes and without self-propelled motion to take the animateness out of the shapes. In this case, the pushing up or pushing down of the red circle can no longer be called “helping” and “hindering,” respectively, and so, the interaction of shapes is no longer social. And strikingly, in this case, infants do not choose the pusher-up shape significantly more than the pusher-down shape. Their choosing behavior differs significantly from the first experiment that used animated shapes (Hamlin et al. 2007).

This result shows that infants are not just making mere perceptual preferences but are making social evaluations in particular. Additionally, the fact that such social evaluatory behavior emerges so early in life suggests how important cognitive mechanisms of social evaluation are and how fundamental they are to perceiving and slicing our social worlds based on valuations of agentic behavior. While this social preference in itself is not evidence of tribalism in infants, it does show that categorizing morally relevant behavior is a

fundamental process of social evaluation, which later on in life becomes a key feature in forming and joining tribal alliances (Pietraszewski 2016; Tooby and Cosmides 2010).

An important feature of human social life is that people sometimes discriminate between in-group and out-group members. They tend to evaluate in-group members more positively than out-group members, reward in-group members more than out-group members, and work harder to accomplish in-group goals (Tajfel 1982). The favoring of in-groups is often likely to be an impediment to organizations, communities, and societies, which to a large degree rely on in-group–out-group cooperation and coordination around common goals.

On the other hand, in-group favoritism may help the overall functioning of a group and promote the in-group individual’s long-term benefits including increased survival and reproductive benefits, because cooperating with groups is often necessary to achieve social goals that are necessary for human life (Clark et al. 2019). Favoring in-groups and disfavoring out-groups creates intergroup bias and conflict (Balliet et al. 2014; Schiller et al. 2014). This can lead to hostile tensions and competition between groups that express themselves in different domains of social life, such as war and politics (Pietraszewski et al. 2015; Wrangham 1999).

Evidence from studies using the implicit association test have shown how rapidly and automatically people assign negative qualities to out-group members, for example, people of a different race and gender (Greenwald et al. 1998). But these studies have not only shown how inclined humans are to assign negative qualities to out-group members but also how automatically we slice the social world into Us and Thems in the first place. These studies show how automatically and unconsciously people are perceiving (and inventing) group differences and imbuing these differences with meaning. However, one has to take some of these studies with a grain of salt as some have failed to replicate in recent years (Boniecki and Jacks 2002), and some researchers have advocated caution in interpreting these overt, explicit discrimination and prejudice from evidence of

implicit associations (Arkes and Tetlock 2004; Boniecki and Jacks 2002).

Many social psychology studies have examined the nature of cooperation and competition with in-groups and out-groups (Schiller et al. 2014; Tajfel 1982). Such research has assessed how intergroup bias manifests in decision-making, trust, reciprocation behavior, and rewarding in-group versus out-group members (Balliet et al. 2014). However, research has been divided over the question of how intergroup discrimination emerges. Some studies have stressed the importance of in-group favoritism while others have stressed the importance of the presence of out-groups against whom in-groups can aggress. It is also plausible that both are at play (Balliet et al. 2014).

Theories of Social Cooperation

Findings from classic studies in social psychology have shown that people will engage in intergroup discrimination to, for example, maximize differences in rewards between in-groups and out-groups (Tajfel et al. 1971; Balliet et al. 2014). Tajfel and colleagues pioneered the use of what is called the minimal group paradigm, which are the minimal conditions that would create in-group behavior, to study in-group–out-group dynamics (Hogg 2016; Tajfel et al. 1971). In such conditions, group adherence alone is enough to create intergroup discrimination even when members are randomly assigned to groups, have no personal connection or information about the members of one's in-group or out-group, and no communication with them (Hogg 2016). This central finding has stood the test of time and has been replicated numerous times with varying methodological procedures, across a variety of participant characteristics (Hogg 2016).

Balliet et al. (2014) conducted a meta-analysis of intergroup discrimination and in-group favoritism in cooperation and assessed multiple predictions from two theoretical perspectives. One is social identity theory (SIT) (Tajfel and Turner 1979) and the other is bounded generalized reciprocity (BGR) (Yamagishi et al. 1999). They offer

predictions regarding moderating conditions of intergroup discrimination. For example, BGR stresses the importance of indirect reciprocity and the importance of reputation in cooperation where the theory predicts that in-group favoritism should occur in the absence of an out-group. However, SIT relies on the presence of an out-group to make the in-group categorization meaningful. Balliet et al. (2014) assesses competing and shared hypotheses between these two theories. The study also weighs in on the question of whether intergroup discrimination is the result of in-group favoritism or out-group derogation.

While the meta-analysis found support for both theories in explaining intergroup discrimination, it did support more predictions that were in line with BGR. For instance, in contrast to this prediction of SIT, people do cooperate more with in-group members compared to unclassified strangers, suggesting that the presence of an out-group is unnecessary for in-group favoritism to emerge. This finding also supports BGR in that mere cues of in-group membership elicited enhanced cooperation toward in-group members. Balliet et al. (2014) also found that the possibility of direct reciprocity weakened in-group favoritism. In-group favoritism in cooperative decision-making rests on expectations of indirect reciprocity within one's in-group and is weakened by expectations of direct reciprocity. They show that there was a significant difference between social dilemmas and trust games, with weakened in-group favoritism in the latter, supporting the BGR perspective.

Tribalism in the Modern Day

Much of tribalism in the modern day is in the form of political conflict, which has arguably increased in the wake of the 2016 American Presidential election with the rise of both left- and right-wing extremist groups, if not in actual numbers, at least in popularity in the media. A recent meta-analysis examined the question of whether liberals or conservatives tend to be more politically biased in the following way: selectively evaluating information more favorably when it supports one's political

beliefs than when it challenges them (Ditto et al. 2018). The meta-analysis examined over 51 experimental studies on partisan bias involving over 18,000 participants. Ditto et al. (2018) found evidence for roughly equal levels of partisan bias among liberal and conservative participants across the studies, and across various methodologies.

Engaging in such biased information processing is just one of the many forms of cognitive biases that take on a tribal function. Evaluating information more favorably when it aligns with one's group affiliation is a way to display loyalty to the groups to which one belongs and as well as denounce a rival group. It also likely leads one astray from an accurate understanding of reality since information is being selectively processed and evaluated on the basis of group loyalty rather than truth.

Kahan et al. (2017) found that subjects highest in numeracy – the ability to understand and make use of quantitative data – were better able to solve a difficult apolitical problem compared to people lower in numeracy. However, individuals high in numeracy were also poorer performers when the same data was politicized – that is, presented as the results from a study on gun control. These tribal differences in the political realm map onto differences in moral values between Democrats and Republicans that have been examined by moral psychologists (Graham et al. 2009; Haidt and Graham 2007).

Tribalism and the Coronavirus Pandemic

At the time of this writing, the world has been experiencing the coronavirus (COVID-19) pandemic, to which the response in the United States has been tribal. In other words, an inherently apolitical and amoral infectious disease has come to be perceived politically and morally. This is because the objective existence of the pandemic has been refracted through the lens of subjective, biased, ignorant, tribal human perception.

On the face of it, one ought to doubt that a virus, which infects, spreads, and kills individuals regardless of their socioeconomic status or political affiliation would come to be perceived and

treated differently by certain individuals. On the contrary, the doubtful would be proven wrong. In this case, the relevant tribes to which these individuals with differing information about the coronavirus pandemic belong are political tribes, which can be loosely categorized as conservative on one side and liberal on the other. Indeed, since the outbreak began in the United States, these two tribes, as represented in the government and in the media, have been espousing divergent information about the threat that COVID-19 poses to the American people. The cloud of misinformation has grown to include the severity of the virus, recommendations for how to slow the spread, and the relative importance of preventing deaths at the expense of harming the economy.

A recent NYTimes Op-ed displayed the extent of this political bifurcation in American political life (Plott 2020). The article shows how at least some of President Donald Trump's supporters perceived Trump's response to the coronavirus threat in a very different way than others. While many others took Trump's response to be an unambiguous dismissal of the coronavirus threat to the United States, they instead saw it as Trump's attempt to "stay positive and not incite panic" (Plott 2020).

Recent research shows that, indeed, political tribalism plays a significant role in explaining the reaction of the American public to the coronavirus threat. Specifically, political partisanship better accounts for the differentiation between Americans' health behaviors and policy preferences in regards to COVID-19 than any other factor tested, such as race, marital status, age, income, education, and region of residence (Gadarian et al. 2020). In particular, Gadarian, Goodman, and Pepinsky (2020) show that Democrats are more likely than Republicans to report having adopted a set of health behaviors, such as frequent hand washing, that collectively reflect social distancing. Democrats also reported showing more worrying attitudes towards COVID-19, such as there not being enough testing and that they, along with their friends, will get sick. In contrast to Democrats, Republicans are more likely to support policies restricting trade and movement across borders, whereas Democrats are more likely to

report conforming to CDC-recommended behavior, changing their personal health behaviors, and supporting more socializing policies in response to COVID-19 (Gadarian et al. 2020).

Zooming out from the tribal response to the coronavirus pandemic within the United States, we can also view how differences between cultures in the degree of within-group cooperation and norm-enforcements encourage different responses to the pandemic. Research shows that in addition to government efficiency, the adoption of cooperative norms is essential for the effective response to a collective threat, such as the coronavirus pandemic (Gelfand et al. 2020). In other words, societies that are better able to deal with collective threats not only have governments that can efficiently coordinate institutions to allocate resources to solving collective problems, but also possess cultural and social norms that encourage cooperative norms and punish deviation from those norms (Gelfand et al. 2020). These are often known as “tight” cultures, which overlap with collectivist cultures such as China, as opposed to loose or individualist cultures, such as the United States.

This operationalization of cooperation within cultures is highly related to tribalism, since tight or collectivist cultures do possess more behaviors and tendencies that relate to valuing, favoring, and supporting their in-groups, which often comprise of familial, ethnic, and ethnolinguistic ties (Gelfand et al. 2020). These cultural and social differences between countries in dealing with the coronavirus have very real effects on the rates of infection and mortality for individuals (Gelfand et al. 2020). Indeed, Gelfand et al. (2020) found that nations with higher levels of government efficiency and cultural tightness have lower infection and mortality rates compared to looser cultures with less government efficiency.

Conclusion

In many ways, tribal behavior taps into what Pinker (2011) refers to as our inner demons, which form the main portion of this work. However, there is a bright side to the fact that humans

are tribal creatures. Because we can create tribal identities and categorizations so readily and quickly around a variety of different concepts, we can also leave them quickly and reform and expand them to include more in-group members. Perhaps this process of greater inclusivity is behind what moral philosopher Peter Singer referred to as the expanding circle of empathy (Singer 1981) and one of the reasons behind what some scholars have attributed the decline of violence to (Pinker 2011). As we face new challenges and become a more interconnected species, understanding our tribal nature becomes increasingly important. Only then can we hope to counteract its negative features.

Definition

The mechanisms that promote kin selection, which is the process whereby traits and behaviors evolve because of their impact on the reproductive success of their bearer's close relatives.

Introduction

Charles Darwin's theory of evolution by means of natural selection set the stage for explaining the appearance of organismal design in the natural world (Darwin 1859), a problem that was famously outlined by William Paley in his book *Natural Theology*: if a watch requires a watchmaker, then organismal design requires a *designer*, to put it simply. In his influential book *On The Origin of Species*, Darwin argued that organismal design is the product of a process he called natural selection, a process that occurs whenever populations show variation among individuals, when this variation is associated with reproductive success and is at least partially inherited from parents to offspring (Darwin

1859). Characters that confer a survival or reproductive advantage upon their bearers are passed on from parents to offspring, and their frequency gradually increases in the population, a process that over long timescales leads to the accumulation of beneficial characters in a population and to organisms being adapted to their environment.

A major puzzle that remained in the wake of Charles Darwin's theory of natural selection was the evolution of altruism. In a world where individuals strive to pass on copies of their genes to future generations, it is difficult to explain why in some cases individuals seem to be designed to voluntarily give up some (if not all) of their own reproduction to help with the reproduction of their social partners. Darwin himself discussed the problem of altruism in *On The Origin of Species* as one of the special difficulties faced by his theory of natural selection. In this *Origin's* passage, he employed a kin selection argument to explain altruism, where he focused on the evolution of sterile castes in social insects. If natural selection works by the transmission of beneficial characters from parents to offspring, he reasoned, how could insect workers, who do not reproduce, transmit their altruistic characters to the next generation? He argued by analogy. Tasteful vegetables are destroyed when cooked, yet horticulturalists can cultivate these tasty variants repeatedly by choosing seeds from the same stock; likewise, tasty meat can be produced again by choosing animals from the same family. Darwin concluded that sterile workers had their origin in a similar process, in which "family" selection operates so that worker traits are passed on to the next generation by the reproductive individuals in the family (i.e., the queens), even if these reproductive individuals do not express the worker traits themselves.

In 1930, Ronald A. Fisher also pondered about the problem of altruism when he discussed the evolution of distastefulness in insects (Fisher 1930). He realized how distastefulness could provide a benefit to a species at large: a predator upon experiencing the distastefulness of an individual would learn to avoid preying upon other individuals of the same species. However, how could distastefulness evolve

by individual selection, he wondered. Fisher also employed a kin selection argument arguing that the selective advantage of distastefulness could be shared among a group of relatives, who are likely to carry and pass on the distastefulness character of the victim. Later, the geneticist J. B. S. Haldane also considered the problem of altruism (Haldane 1955). Haldane questioned why anyone would put her own life in jeopardy by jumping into a river to save a drowning child. He argued that if the two persons were related, helping could indeed be the optimal behavior. While Darwin, Fisher, and Haldane provided us with important insights into the problem of altruism and kin selection, they were unable to provide a comprehensive and general explanation for altruism.

It was William D. Hamilton's theory of inclusive fitness that finally provided a general framework for understanding the problem of altruism in particular and social behavior in general (Hamilton 1964). Inclusive fitness theory posits that individuals are willing to sacrifice some of their own reproduction if by doing so they help genetic relatives passing on copies of their own genes to future generations. This idea is encapsulated in the inequality $-c + br > 0$, which is widely known as Hamilton's rule and where c is the cost paid by the actor, b is the benefit provided to the recipient, and r is the relatedness between the actor and the recipient of the behavior. Altruism evolves if the benefit and relatedness are sufficiently high, and the cost is sufficiently low. Hamilton's inclusive fitness theory expands Darwin's concept of fitness and defines two paths through which individuals can generate fitness: direct (i.e., $-c$) and indirect fitness (i.e., rb). Kin selection operates when a behavior evolves because it increases the indirect component of an individual's inclusive fitness. The term kin selection itself owes its origin to John Maynard Smith (1964) and is widely used because the most common form of generating indirect fitness benefits is when social partners share a recent common ancestor.

Kin Selection and Hamilton's Rule

Ultimately, evolution is defined as the change in gene frequency over time, which can occur

through natural selection but can also occur through other nonadaptive processes such as migration, mutation, and genetic drift. The Price equation provides a general description of an evolving population, which can be used to formulate the foundations of kin selection theory (Price 1970; Queller 1992; Frank 1997; Gardner et al. 2011). The Price equation framework is based on the mapping between two populations, usually denominated by the parental and offspring populations. Parents are characterized by their breeding value (i.e., the heritable component of their phenotype) and their number of offspring, and offspring are characterized by their breeding value. The Price equation focuses on the change in average breeding value (i.e., $\Delta\bar{g}$) from one generation to the next. Total change in breeding value can be either due to natural selection (NS) or transmission. Here we are interested in adaptive evolution, and therefore we will focus on the natural selection component of the Price equation. The average change in breeding value from one generation to the next owing to natural selection is then given by

$$\Delta_{\text{NS}}\bar{g} = \text{Cov}(w, g), \quad (1)$$

where w is the relative fitness of a focal individual, where g is its breeding value, and where the covariance is taken across all individuals in the population. If we expand the Price equation we get $\Delta_{\text{NS}}\bar{g} = \beta_{w,g}\text{Var}(g)$, where $\beta_{w,g} = \text{Cov}(w, g)/\text{Var}(g)$ is the regression coefficient of fitness on the breeding value of the focal individual. This provides a mathematical expression of the three principles that must be satisfied if natural selection is to occur: there must be heritable variation in the population (i.e., $\text{Var}(g) > 0$), and heritable variation must be associated with fitness (i.e., $\beta_{w,g} \neq 0$).

In a social context, however, the fitness of a focal individual depends not only on her own breeding value (g) but also on the breeding value of her social partner(s) (G). In such cases, the regression coefficient $\beta_{w,g}$ can be partitioned into two components by using partial regression coefficients. The Price equation becomes

$$\Delta_{\text{NS}}\bar{g} = \left(\beta_{w.g|G} + \beta_{w.g|G} \frac{\text{Cov}(g, G)}{\text{Var}(g)} \right) \text{Var}(g) \quad (2)$$

where $\beta_{w.g|G}$ is the regression coefficient of an actor's fitness on an actor's breeding value, holding the social partner's breeding value constant; $\beta_{w.g|G}$ is the regression coefficient of a recipient's fitness on an actor's breeding value, holding the social partner's breeding value constant; and $\text{Cov}(g, G)/\text{Var}(g)$ is the regression coefficient between an actor's breeding value and a recipient's breeding value. We thus arrive at Hamilton's rule, the condition for the evolution of a social trait, which is given by

$$-c + br > 0 \quad (3)$$

where the cost to the actor is $c = -\beta_{w.g|G}$, the benefit to the recipient is $b = \beta_{w.g|G}$, and the coefficient of relatedness is $r = \text{Cov}(g, G)/\text{Var}(g)$ and where we assume that there is heritable variation in the population (i.e., $\text{Var}(g) > 0$).

Hamilton's rule extends the concept of Darwinian fitness to include the effects of a focal actor on the fitness of her social partners by partitioning fitness into direct ($-c$) and indirect fitness (br). Hamilton's rule not only establishes the direction of selection but it also provides a causal model of how fitness is achieved by a focal actor. Both Eqs. 1 and 2 offer an answer to which breeding values evolve; however, they presuppose different underlying causal models (see Fig. 1).

Hamilton's rule allows for the classification of any social behavior, which can be defined

according to its effect on the fitness of actors and recipients (Hamilton 1964; West et al. 2007; see Table 1). If the behavior is costly to the actor (i.e., $c > 0$) and beneficial to the recipient (i.e., $b > 0$), the behavior is called altruistic. If the behavior provides a benefit to the actor (i.e., $c < 0$) and a benefit to the recipient (i.e., $b > 0$), the behavior is classified as mutually beneficial. If the behavior is costly to the actor (i.e., $c > 0$) and costly to the recipient (i.e., $b < 0$), the behavior is spiteful. Finally, if the behavior provides a benefit to the actor (i.e., $c < 0$) and is costly to the recipient (i.e., $b < 0$), the behavior is defined as selfish.

The Triggers of Kin Selection

Kin selection requires that social interactions occur among related individuals, a scenario that can be generated by three main mechanisms. First, kin discrimination generates high relatedness between social partners owing to a recent common ancestor (Hamilton 1964). Second, the greenbeard effect generates high relatedness at the locus of interest between social partners, irrespective of their genealogical ancestry (Hamilton 1964; Dawkins 1976). Finally, population viscosity, in which individuals tend to remain near their place of birth, generates high relatedness among neighbors, which may even favor unconditional expression of altruistic behavior (Hamilton 1964).

Kin Recognition

Kin recognition occurs whenever individuals are able to discriminate genealogical relatives and requires that individuals are able to identify close relatives among their social partners and direct their social behavior toward these relatives. There are two possible kin recognition mechanisms: genetic and environmental kin discrimination.

Genetic kin discrimination – Genetic kin discrimination relies on the identification of a social partner's trait, which once compared with a template carried by the focal individual can provide a correct prediction of kinship between the two individuals. This requires genetic polymorphism in the population at the

Triggering Kin Selection, Fig. 1 The underlying causal models of Darwinian fitness (panel a) and inclusive fitness (panel b). Inclusive fitness partitions fitness into a direct fitness component ($-c = \beta_{w.g|G}$) and an indirect fitness component ($rb = \beta_{g,G}\beta_{w.g|G}$)

Triggering Kin Selection,
Table 1 Classification of social behaviors according to their effects on the actor and on the recipient of the social behavior

		Effect on recipient	
		$b > 0$	$b < 0$
Effect on actor	$c > 0$	Altruistic	Spiteful
	$c < 0$	Mutually beneficial	Selfish

locus of interest so that there is selective pressure for genetic recognition mechanisms. The selective advantage provided by genetic kin discrimination, however, may lead to the erosion of the polymorphism in the population, which, in turn, selects against genetic recognition mechanisms. Due to this evolutionary instability, it is thought that genetic kin discrimination is relatively rare in nature. Despite this, a few cases of genetic kin discrimination have been identified in the natural world.

Dictyostelium purpureum is a microorganism that usually lives solitarily foraging for bacteria in the soil of forests. When they run out of food, they aggregate to form multicellular mobile slugs that move toward the soil surface. Upon reaching the soil surface, a fraction of cells differentiate and become spore cells, while the other fraction self-sacrifices themselves to form a stalk that enables spore cells to disperse and colonize other areas. This extreme altruistic behavior may be rendered evolutionary unstable if cheater lineages, which preferentially differentiate into spore cells while contributing little to the stalk of the fruiting body, emerge in the population. Mehdiabadi et al. (2006) found that genetic kin discrimination may be responsible for the stability of cooperation in *D. purpureum*. When two lineages are mixed together to form fruiting bodies, lineages seem to recognize each other so that each fruiting body ends up with a very high proportion of cells belonging to a single clone. Later studies have found that the *lag* gene family may account for the discrimination mechanism in *D. purpureum* (Benabentos et al. 2009). It has been shown that *lagB1* and *lagC1* are highly polymorphic in natural populations and that deleting these genes caused these strains to segregate with wild-type cells.

Environmental kin recognition – Environmental kin recognition occurs whenever individuals

learn to recognize each other owing to a shared environment. Individuals that share an environment early in life, for instance, are likely to be relatives, and therefore any cue associated with this early-life shared environment is likely to accurately identify a social partner as a close relative later in life.

Environmental kin discrimination has been identified as a factor that stabilizes cooperation in long-tailed tits. Long-tailed tits are a cooperative breeding species in which individuals who fail to breed may become helpers at someone else’s nest. First, it has been shown that helpers are often found in the nest of close relatives (Russell et al. 2001). Furthermore, individuals who fail to breed only become helpers if they are able to find breeders who are close relatives. In addition, when, in an experimental setup, failed breeders were given the choice between nests of unrelated and related individuals, they often chose the nest of related individuals. A later study revealed that vocalizations play a key role in the underlying kin discrimination mechanism used by long-tailed tits. Vocalizations differ across families, and because they are learned early in the life of long-tailed tits when parents are provisioning young, they are reliable cues of kinship and allow individuals to discriminate between kin and non-kin later in life (Sharp et al. 2005).

The Greenbeard Effect

The greenbeard effect occurs whenever a gene or a cluster of tightly linked genes expresses an identifiable phenotype (i.e., the greenbeard), it is able to identify the greenbeard in other individuals, and it is able to direct its cooperative behavior toward them. The greenbeard effect is thought to be rare in nature because they are prone to invasion by individuals who display the greenbeard but do not perform the altruistic behavior. Despite

this, there are some examples of the greenbeard effect in the natural world, especially in microorganisms and insects.

The eukaryotic microorganism *Dictyostelium discoideum* has a life cycle similar to that of *D. purpureum* as outlined above. When *D. discoideum* cells run out of food, they also form a multicellular fruiting body, in which around 20% of cells self-sacrifice themselves to form the stalk of the fruiting body. Because multicellular cells develop from the aggregation of potentially different clones, the cooperative behavior of slime mold cells may become evolutionarily unstable owing to the invasion of cheater lineages that preferentially place themselves in the fruiting body, but do not contribute to the stalk supporting it. Queller et al. (2003) found that the *csA* gene acts as a greenbeard and therefore stabilizes the cooperative behavior in *D. discoideum*. The *csA* gene encodes the gp80 cell adhesion protein that is anchored to the surface of cells. These proteins bind to gp80 proteins in other cells, and therefore during the cooperative swarming of the multicellular body, they leave behind most of the cheater cells that do not produce gp80 proteins.

Population Viscosity

Population viscosity is when individuals tend to remain near their place of birth. Hamilton suggested that population viscosity could play an important role in the evolution of cooperative behavior because it does not require any sophisticated recognition mechanism to generate high relatedness among social partners (Hamilton 1964). Population viscosity, however, also generates competition for resources among close relatives, which may offset some or all of the positive effects of population viscosity on the evolution of cooperation.

An empirical test of how population viscosity influences the evolution of cooperation has been developed using experimental evolution in microorganisms. The pathogenic bacterium *Pseudomonas aeruginosa* relies on iron to grow. Iron is a major limiting factor to *P. aeruginosa* because Fe (III), the most common form of iron in nature, is insoluble and not readily accessible to them.

P. aeruginosa were able to find a solution to this problem. They secrete siderophores that bind to Fe(III) making it suitable for their metabolism. Siderophore production is a cooperative trait because it is costly to manufacture, while its end product is publicly available. Griffin et al. (2004) manipulated the dispersal patterns of different lineages and found that the production of siderophores is favored when close relatives interact with each other, and competition is global (i.e., competition is not among close relatives). Moreover, they found that when both social interactions and competition occur among relatives, cooperation did not evolve.

Kin Selection at Work

The Monogamy Hypothesis

The key prediction of inclusive fitness is that altruism is more likely to evolve when social partners are close relatives. This has led to the hypothesis that lifetime monogamy could be a crucial factor in the evolution of eusociality (Boomsma 2009). In eusocial species, there is a reproductive division of labor in which workers forgo reproduction to help reproductives (i.e., the queens). Lifetime monogamy is thought to promote eusociality because when females mate with a single male the relatedness between siblings is equal to the relatedness between mothers and their own offspring. As a result, the slightest benefit provided by altruism may be sufficient to make offspring forego their own reproduction and help their parents raise their siblings. One problem with the monogamy hypothesis, however, is that in many extant eusocial species promiscuity, rather than monogamy, is common, which suggests that monogamy is not necessary for the evolution of eusociality. To test the monogamy hypothesis, it is thus crucial to understand if promiscuity is an ancestral or a derived trait of eusociality (Boomsma 2009). Hughes et al. (2008) found that the ancestral state of all eusocial species is in fact monogamy, which provides a strong support for the role of relatedness in the evolution of eusociality, in particular, and altruism, in general.

Coalitions in Wild Turkeys

In some cases, it is possible to directly measure the different variables in Hamilton's rule. Wild turkeys (*Meleagris gallopavo*) provide a notable example where kin selection has been directly tested. During the breeding season, male wild turkeys display in an attempt to attract their female counterparts. Male turkeys can either display solitarily or in coalitions of two to four males. Only the dominant male in the coalition mates; thus, it is puzzling why subordinate males are willing to join a coalition and forego mating opportunities instead of displaying solitarily. Krakauer (2005) found that subordinate males had a significant positive effect on the number of matings and offspring fathered by the dominant male. Specifically, Krakauer found that dominant males had on average 6.1 offspring, while solitary males had on average 0.9 offspring. Furthermore, Krakauer found that the relatedness between dominant and subordinate males was significantly higher than the relatedness between two random males in the population (i.e., $r = 0.42$). If we replace these values in Hamilton's rule, we get $-c + br = -0.9 + 6.1 \times 0.42 = 1.7 > 0$, which shows that kin selection is able to explain why subordinate male turkeys are willing to join coalitions.

Kin Selection and Class Structure

Most of the kin selection theory assumes that the quality of individuals is identical within a population. More recently, however, there has been a growing interest in understanding kin selection when individuals vary in quality (e.g., Rodrigues and Gardner 2013, 2016). Variation in quality may occur whenever individuals differ in a life history or social trait, such as size, weight, social status, or nutritional state. To illustrate how individual quality may affect social evolution, let us consider the evolution of dispersal, a classic kin selection problem (Hamilton and May 1971). Dispersal evolves through kin selection whenever it carries a cost to the dispersing individuals, when dispersal frees up resources in the disperser's natal patch, and when these resources are utilized by the disperser's close relatives (Hamilton and May

1971, reviewed in Rodrigues and Gardner 2016). In such cases, Hamilton's rule, the condition for the evolution of altruistic dispersal, is given by

$$-v + (1 - k)v + vhr > 0 \quad (4)$$

where v is the expected reproductive success of an offspring that remains in the natal patch, k is the cost of dispersal, h is the probability that a native offspring wins a breeding site, and r is the relatedness among native offspring within a patch. The left-hand side of Hamilton's rule readily yields a kin selection interpretation of the behavior. First, a disperser pays a fitness cost v . Second, a disperser successfully arrives at a patch with probability $1 - k$, in which case it derives a fitness benefit of v . Finally, the value of the amount of resources freed up by a disperser is v , which goes to a native individual with probability h , whose relatedness to the disperser is r . The first two terms thus represent the marginal direct fitness of the behavior, while the third term represents the marginal indirect fitness. Let us now consider that there is class structure in the population, with a high-ranking more fecund female (denoted by H) and a low-ranking less fecund female (denoted by L) in each patch, which is often the case in many species ranging from mammals to insects. Under this scenario, offspring of the high-ranking mothers find themselves surrounded by more siblings than offspring of the low-ranking mothers, and therefore it is likely that they express different dispersal behavior (Rodrigues and Gardner 2016). The condition for the evolution of altruistic dispersal is given then by

$$-v + (1 - k)v + v\bar{r}_i > 0 \quad (5)$$

where $\bar{r}_i$ is the average relatedness between the disperser (whose mother has rank " i ") and those who remain in the patch, with $i \in \{H, L\}$. Because offspring of high-ranking mothers have more siblings, we have $r_H > r_L$, which means that offspring of high-ranking mothers are selected to disperse more often than offspring of low-ranking mothers. Surprisingly, Rodrigues and Gardner (2016) found that the number of offspring that remain in the patch is exactly the

same irrespective of the mother's quality (i.e., the "constant philopater hypothesis").

A particular case of class-structured populations is when diploid individuals reproduce sexually. Sex structure is an important factor in the analysis of the evolution of social dispersal of females and males in human populations. Nitsch et al. (2016) studied the evolution of human sex-specific dispersal in preindustrial Finland, where they have analyzed how the presence of same-sex and opposite-sex elder siblings influenced the dispersal behavior of later-born siblings. They found that the presence of same-sex elder siblings have a strong effect on the dispersal behavior of later-born siblings, while the presence of opposite-sex siblings has a weaker effect. Specifically, they have shown that younger siblings tend to disperse more when there are older siblings present in the population.

Summary

Kin selection is a process by which traits evolve owing to their effect on the fitness of their bearer's relatives. These indirect fitness effects can be generated through three different mechanisms. Kin discrimination leads to interactions among individuals who share a recent common ancestor. Kin discrimination can be genetic, in which individuals are able to recognize kin through a genetic template, or environmental, in which recognition emerges from cues associated with a shared environment. The greenbeard effect allows for altruism among genetic relatives, irrespective of their genealogical ancestry. Finally, population viscosity leads to neighboring individuals being close relatives, and therefore it may even allow for the evolution of indiscriminate altruism. Kin selection occurs at all levels of biological organization, and it is key for the evolution of cooperative behavior, from the evolution of sterile castes in eusocial insects to the evolution of parental care. Finally, kin selection also plays a crucial role in the evolution of major evolutionary transitions, such as the evolution of multicellularity, in which lower level biological units cooperate to form a cohesive and functional higher level biological unit (Fisher et al. 2013).

Trivers-Willard Effect

► [Robert Trivers](#)

Trivers-Willard Hypothesis

Jaime Palmer-Hague

Trinity Western University, Langley, BC, Canada

Definition

Hypothesis that natural selection favors parental ability to alter offspring sex in the direction that maximizes their own reproductive success.

Introduction

Trivers and Willard (1973) proposed that in order to maximize their own long-term reproductive

success, it would advantage parents if they could alter the sexes of their offspring. More than 40 years of research have attempted to confirm this hypothesis, but with mixed results. In humans, several lines of evidence suggest that parents who exhibit characteristics associated with increased male reproductive success have more sons than those who do not. Dominance, in particular, provides both an adaptive and plausible characteristic by which the Trivers-Willard hypothesis might operate. Evidence in support of this possibility comes from four areas: (1) offspring sex ratios of fathers demonstrating characteristics of dominance, (2) offspring sex ratios of mothers demonstrating characteristics of dominance, (3) parental hormones and offspring sex ratios, and (4) assortative mating and offspring sex ratios.

Parental Variation of Offspring Sex

In their seminal article, Trivers and Willard (1973) hypothesized that natural selection should favor parental ability to alter the sexes of their offspring in the direction that maximized their own reproductive success. Now widely known as the Trivers-Willard hypothesis (TWH), their paper proposed that mothers and fathers in good condition (i.e., those who possessed some characteristic or trait ultimately favoring male future reproductive success relative to female reproductive success) should produce more sons. Those sons, in turn, would inherit their parent's good condition and thus obtain greater access than other males to female mates and thus produce more offspring. In contrast, parents in poor condition would maximize their reproductive success by having daughters. The reasoning here is that inheritance of poorer condition would have less impact on a daughter's access to mates than it would for a son's, and her production of offspring would remain relatively stable.

The TWH relies on three assumptions: (1) that parental condition during parental investment reflects the condition of the offspring at the end of parental investment, (2) that this variation in offspring condition persists into adulthood, and

(3) that offspring condition preferentially aids male reproductive success compared to female reproductive success. Using a hypothetical population of caribou as a working example, Trivers and Willard (1973) focused largely on maternal condition (i.e., body weight). They argued that assuming that mothers with higher body weight are better able to provide nutrition to their calves, they would be better suited to have a son. The nutrition a son received would, theoretically, render him larger, stronger, and healthier than other calves. Assuming that he retained these traits until adulthood, the son should be more successful in competitions with other males for female mates, thus producing more grand offspring for his mother. Of course, this example also assumes that large body size, strength, and health are more strongly associated with male compared to female reproductive success in adulthood, thus facilitating greater reproductive benefit for a male than a female offspring.

It is important to note that the TWH is a *theoretical* evolutionary hypothesis focused on ultimate rather than proximate causes of sex ratio variation. In other words, the authors did not propose any explicit mechanisms by which parental ability to vary offspring sex might occur. They also did not provide an exact definition of parental “condition.” As variation in environments, mating systems, and ecological characteristics of animal populations occur, this information is also variable, but it is not crucial for understanding of the underlying principle of how the TWH would operate.

The open-ended nature of the TWH, however, is likely why despite its simplicity and elegance, results from more than 40 years of research have failed to generate consistent evidence that parental condition does, in fact, lead to biased offspring sex ratios. Although variation in maternal condition has been associated with male-biased offspring sex ratios in several mammalian species including humans, this is not always the case (for reviews, see Brown 2001; Brown and Silk 2002; Clutton-Brock and Iason 1986; Hardy 1997; Hewison and Gaillard 1999; Hiraiwa-Hasegawa 1993). One possible reason for the discrepancy is that many researchers have focused

on parental investment (i.e., provision of resources to offspring after birth), whereas many others have focused on either primary (i.e., number of males and females at conception) or secondary sex ratios (i.e., number of males and females at birth). Similarly, because there is no explicit definition of “condition,” researchers have looked largely at physiological rather than behavioral indicators of quality, such as age, physical size, and nutritional status. In addition, virtually all research investigating the TWH has focused on maternal status, allowing no potential influence for paternal condition on offspring sex. When contributing sources of variance are considered, however, a clearer picture of TWH operation in mammals begins to emerge.

In a meta-analysis of the literature involving ungulates, Sheldon and West (2004) found only marginal support for the TWH. However, when they analyzed studies that looked specifically at maternal behavioral dominance (i.e., a female’s ability to compete for resources), they found effect sizes four times larger than those looking at physiological indicators. Although exclusive to ungulates, those results suggest that maternal rank could be more than a simple proxy for physiological status, as has been assumed in much of the research with nonhuman primates. Indeed, Cameron (2004) found significant heterogeneity among studies that looked at maternal dominance and offspring sex for mammals. This suggests that the factors defining favorable “condition” may be considerably more complex than simply physical parameters, such as weight or body size. For example, epigenetic influences, such as parental behavior, could impose reproductive benefits on offspring through social interaction.

Another important factor is whether parental condition at conception, birth, or after birth (i.e., parental investment) is studied as part of the TWH. Although Trivers and Willard (1973) used the illustration of a female nursing of her calf as increasing its size, they did not specify that the mechanism through which parent condition might benefit offspring should necessarily be post-conception. In fact, the evidence in support of facultative adjustment of offspring sex *peri-conception* is much more convincing. Both

Sheldon and West (2004) and Cameron (2004) have demonstrated substantially larger effect sizes from studies evaluating maternal condition around the time of conception compared to post-conception. This suggests that any parental manipulation of offspring sex may be the result of preexisting differences prior to sex determination and therefore variable and dependent on environmental factors.

Offspring Sex Ratios and Characteristics of Dominance in Fathers

A variety of physiological and behavioral characteristics associated with both dominance and increased male, but not female, reproductive success (reviewed in Campbell 1999; Puts 2010; Puts et al. 2012) have been identified for fathers who have more sons. For example, more sons have been observed in families of fathers who are heavier and taller compared to fathers who are lighter and shorter (Kanazawa 2005; but see Gelman 2007 and response in Kanazawa and Reyniers 2009; Manning et al. 1996). This suggests that physical indicators of dominance may be associated with more male offspring in men.

Interestingly, indicators of paternal dominance behavior are also associated with more sons than daughters. Cameron and Delerum (2009) showed that male billionaires, as well as sons of male billionaires, had significantly more sons than daughters. They also had more sons than would be expected in the general population. Although it is possible that this finding more appropriately supports parental investment in offspring (i.e., provision of resources such as food, shelter, health care) rather than parental dominance traits as affecting primary sex ratios, additional evidence showing temporal changes in offspring sex ratios (i.e., from male-biased to balanced) of US presidents (Betzig and Weber 1995) suggests that psychological influences are more likely. In addition, lower (i.e., more masculine) 2D:4D ratios, which have been shown to indicate men's dominance and masculinity (Neave et al. 2003), as well as correlate positively with self-reported attractiveness in men (Manning and Quinton 2007), have been found in fathers with higher sex ratios (i.e., more sons than daughters) (Manning et al. 2002).

Further, both unrestricted attitudes toward sexuality (e.g., favoring promiscuity) (Kanazawa and Apari 2009) and violent (i.e., aggressive) behavior, both of which are involved in men's social hierarchies, also predict more sons (Kanazawa 2006). Indeed, fathers who score higher on measures of behavioral dominance are also more likely to have a first-born son than daughter (Palmer-Hague and Watson 2016a). Taken together, various studies suggest that both physical and behavior markers of a male's capacity to be dominant may be correlated with a tendency for him to sire more sons as predicted by the TWH.

Offspring Sex Ratios and Characteristics of Dominance in Mothers

The TWH predicted that maternal influences could also bias offspring sex ratios. Indeed, dominance characteristics in mothers do appear to bias offspring sex ratios in ways congruent with the hypothesis. Physical features such as female body size are related to higher (i.e., more males) offspring sex ratios. Taller and heavier mothers also have more sons than shorter and lighter mothers (Kanazawa 2005; but see Gelman 2007 and response in Kanazawa and Reyniers 2009; Manning et al. 1996). Women with greater muscle mass in their upper arms – a proxy for nutritional status (i.e., greater resource acquisition ability) – also have more sons (Gibson and Mace 2003). Although larger size is indicative of physical characteristics, such as glucose availability or nutritional stores, a large body of evidence suggests that these factors are all also functionally related to maternal dominance.

Women who score higher on behavioral dominance measures are significantly more likely to have a son than women who score lower (Akande 1999; Grant 1990, 1994; Palmer-Hague and Watson 2016a). In addition, lower-ranking co-wives (i.e., lower status) in Rwandan marriages do have more daughters than higher-ranking co-wives (Pollett et al. 2009), suggesting that maternal dominance is functional in determining offspring sex. Interestingly, Gangestad and Simpson (1990) found that more extraverted, less behaviorally restrained women had more sons than those who

were less extraverted and more behaviorally restrained. Women who exhibit high ranking in social hierarchy, therefore, are not only likely to have increased access to resources important for offspring survival (e.g., food) but also to exhibit behaviors relevant to interpersonal competition and status. This would preferentially benefit sons compared to daughters when it comes to accessing mates.

Parental Hormones and Offspring Sex Ratios

Variation in male and female reproductive hormones is a plausible mechanism for altering offspring sex. As decades of research in social neuroendocrinology indicate, reciprocal relationships exist between hormones, behavior, and the environment. For example, hormonal response to competition and interpersonal challenge (e.g., increases in testosterone with successful interaction), variation in nutrition and caloric availability (e.g., increases in cortisol in response to low calorie diets), and motherhood (e.g., increases in prolactin in response to infant feeding) are all examples where hormone levels change in response to the environment. In turn, these changes can alter an individual's physiology (e.g., testosterone increases vigor and muscularity), behavior (e.g., success in competition), and future experience (i.e., willingness to engage in competition) (reviewed in Hamilton et al. 2015). Although an exact mechanism remains to be identified, there is support for the role of periconception parental hormones in providing a pathway through which dominance can alter offspring sex as predicted by the TWH.

James (1980, 1986) first theorized that increased levels of parental estrogen (E) and testosterone (T) increase the probability of conceiving sons and increased levels of gonadotropins (i.e., luteinizing hormone (LH) and follicle-stimulating hormone (FSH)) increase the probability of conceiving daughters. Although several lines of correlational evidence from epidemiology support of this hypothesis (James 1996, 2008), the process by which paternal hormones could actually alter the probability of a male or female offspring being conceived remains unclear. One possibility is that paternal hormones manipulate

the proportions of X- and Y-chromosome-bearing sperm in seminal fluid (see Edwards and Cameron 2014), but this remains to be investigated.

In contrast, the maternal dominance hypothesis (Grant 1998) predicts that more dominant women can increase their reproductive success by producing sons, and higher levels of endogenous testosterone in these women favor conception of males over females. Specifically, this hypothesis predicts that maternal dominance (i.e., a combination of inherent female traits (e.g., influential, authoritative) that facilitates the changing of another's view or actions) during the period of parental investment is crucial for her son's reproductive success in adulthood. In other words, to some degree, her sons eventually display dominant behavior in response to her dominant interactions with them and others. By producing a dominant son who will successfully outcompete other males for mates, rather than a dominant daughter whose reproductive success will be unaffected, she can enhance her own fitness.

The maternal dominance hypothesis proposes that endogenous maternal testosterone at the time of conception facilitates the reception of a Y-chromosome-bearing sperm by the woman's ovum. This has been demonstrated in bovine ova contained in follicles with elevated fluid testosterone concentrations (Grant and Irwin 2005). Similarly, female rhesus macaques that gave birth to sons were not only more behaviorally dominant (i.e., more successful in displacing conspecifics in direct interactions for food) but also had higher preconception testosterone levels (Grant et al. 2011). Dominance behavior can be both stable and persistent (i.e., a trait) and variable and transient depending on environmental circumstances (i.e., a state). Thus, the maternal dominance hypothesis also explains how the probability of a given woman having either a male or female offspring can vary with each conception.

Although yet to be directly investigated, the maternal dominance hypothesis could also relate to paternal manipulation of offspring sex ratio. For example, more dominant women might choose to mate with more dominant men to facilitate the provision of certain characteristics in her

son (i.e., “good genes”). Interestingly, this would introduce a potential combined parental influence on the production of male or female offspring.

Assortative Mating and Offspring Sex Ratio

Assortative mating based on characteristics that would enhance the reproductive success of male or female offspring presents another possible mechanism through which the TWH might operate. Recent evidence suggests that women who score higher in self-reported dominance (i.e., possessing characteristics that facilitate the changing of another’s views or actions, such as influential or authoritative) are more likely to predict they will have sons (Palmer-Hague et al. 2013). In addition, Palmer-Hague and Watson (2016b) found that women who scored higher in self-reported dominance and predicted they would have sons were also more likely to choose a male described as behaviorally dominant as a potential mate. Retrospective analyses of parents reveal that those scoring higher on measures of behavioral dominance were more likely to have had a firstborn son than a firstborn daughter (Palmer-Hague and Watson 2016a). These results suggest not only that there is some mechanism by which women can evaluate which sex of offspring they are most likely to produce at a given point in time but also that they might differentially choose mates to enhance the reproductive success of this offspring, based on its sex. Similar results were not found for men (Palmer-Hague et al. 2013; Palmer-Hague and Watson 2016b). Thus, manipulation of offspring sex might be under exclusive control of mothers.

Conclusion

In humans, evidence supports the idea that parents can to some extent manipulate their own offspring sex ratio as predicted by TWH. This appears to involve processes related to the expression, attainment, and evaluation of dominance (i.e., condition) by both men and women and that underlying hormonal processes could facilitate conception of either sons or daughters. Testosterone, which is related to a variety of physical and behavioral

characteristics associated with dominance and may actually facilitate the conception of sons, is a plausible candidate.

Or Would You Throw the Fat Man Off the Bridge? A Philosophical Conundrum (Cathcart 2013), the trolley problem is discussed and dissected in its most classic version and several other versions (e.g., the fat man version). These discussions revolve around a fictional court case where a jury is presented with arguments derived from moral philosophy to judge the trolley problem and several alternative versions. The book delves into other broad topics that have implications for ethics and moral reasoning.

Definition

Thomas Cathcart's book, *The Trolley Problem, Or Would You Throw the Fat Man Off the Bridge?: A Philosophical Conundrum*, is an examination of the famous trolley problem and why this is important to philosophers, scientists, and lay people alike.

Introduction

The trolley problem is a philosophical thought experiment that has existed in several iterations. In Thomas Cathcart's book *The Trolley Problem*,

Thomas Cathcart's book, *The Trolley Problem, Or Would You Throw the Fat Man Off the Bridge?: A Philosophical Conundrum* (2013), is primarily about the famous trolley problem, but it also proposes other issues, such as the difference between moral intuition and moral reasoning, the difference between utilitarian and deontological morals, what the naturalistic fallacy is, what an analogy is for, and basic information about classic philosophers. Thomas Cathcart's approach is to present the famous trolley problem in a unique circumstance. The trolley problem asks the reader to imagine that they find themselves standing at a railway switch with a tough choice to make. A trolley is barreling down the tracks toward a group of five people. Those five people will most definitely be killed if the trolley collides with them. Fortunately, the railway switch will divert the trolley down a separate rail line. Unfortunately, a lone individual stands on that stretch of rail. The reader is in a difficult position: if they do nothing, they allow five people to be killed, but if they act, they doom someone else who is otherwise innocent to die. This problem is so infamous that the study of it and other similar problems has been dubbed *trolleyology*. At its core, trolleyology is an exercise in understanding how people come to a conclusion about what they would do if they were standing at the rail switch. Will they pull it or will they leave it alone?

The Trolley Problem presents this classic dilemma as if a woman named Daphne Jones in San Francisco was actually presented with such a situation and she chooses to pull the switch, killing one man to save the lives of five. In this scenario, the case is being brought before the

Court of Public Opinion, a fictional court that establishes precedent based on the opinions of a large number of people (similar to a survey) to determine if Daphne Jones should be praised for making a tough choice to save the greatest number of people or admonished as someone who played God. The remainder of the book is presented as a series of different people, all of whom have different perspectives, backgrounds, and professions, making the case for why they believe that Daphne Jones is either innocent or guilty.

To Pull or Not to Pull the Switch

According to Thomas Cathcart (2013), the argument in favor of pulling the switch to sacrifice one person to save five others is often argued from a utilitarian perspective. Utilitarianism is a branch of moral reasoning that claims that all actions should be assessed for the amount of utility that they possess. In other words, does an action cause the greatest amount of happiness compared to alternatives? In this case, pulling the switch represents an action which maximizes utility because it results in a situation where five people are spared at the expense of one, whereas the alternative is a situation where five perish and one will survive. The counterargument is presented as the deontological perspective, where actions are assessed as rules that we should follow. According to Thomas Cathcart (2013), the deontological perspective dates back to Immanuel Kant, and the logic of it follows that if an action is being considered, first consider a world where that action was utilized in every possible situation. In other words, the deontological perspective applied to the trolley problem presupposes a world where people are always willing to sacrifice the lives of a few people to save the lives of more people. The reason that the deontological perspective is an argument against pulling the switch is because there is no rule that the bystander should interfere in the trolley scenario and the act of interfering presupposes that the bystander needed to interfere to do good.

As Thomas Cathcart lays out this discussion, he opens the door to several other big questions. First, this brings up the question of what “good” means. According to Cathcart (and other classical

philosophers; reviewed in Cathcart 2013), it is impossible to define what good means. While it is often clear when one option is better than another, to say that one is the good choice and another is bad requires an enormous amount of perspective. Next, it opens the door to several other versions of the trolley problem. For example, what if instead of pulling a switch to stop the trolley, the only option afforded to the bystander was to push a nearby fat man onto the tracks so that the trolley would be stopped by his mass? Cathcart identifies that in most studies of the original trolley problem, over 90 % of those surveyed believe that pulling the switch is the correct choice. In this iteration of the trolley problem, 10 % or less of those surveyed believe that they should push the fat man onto the tracks. It is in these differences where the interesting psychological phenomena occur.

After establishing that people predominantly support pulling the switch, but not pushing the fat man, Cathcart (2013) notes that these results are consistent across gender, age, level of education, and even exposure to moral philosophy in general. However, the reasoning that people give for supporting pulling the switch changes along these same lines. For example, women are more likely to think about the relationship that they have with the people involved in the scenario, whereas men are more likely to be utilitarian in their approach. Women tend to consider how the decision will impact the family and friends of those involved. If the scenario is manipulated so that their relatives are the people in the way of the trolley, they will be even more likely to want to sacrifice someone else. Men, on the other hand, tend to make the decision as a form of moral calculus, identifying the option that results in the fewest casualties and going with that option. Further, when modern, young people are asked why they would pull the switch or why they would not push the fat man, their analysis boils down to an intuitive, gut feeling. Cathcart implies that this lack of ability for modern young adults to walk through their moral reasoning is a unique phenomenon. Indeed, when older individuals are faced with similar moral dilemmas, they tend to put effort into explaining why they believe one

choice is correct (i.e., it seems unfair to push the fat man off the bridge because he was not involved in the trolley incident at all), whereas younger individuals tend to rely more on their gut reaction (i.e., it just feels wrong to push him).

Why the Trolley Problem Matters

This brings up another interesting discussion in *The Trolley Problem* in a chapter where a psychologist gives their opinion: the psychologist argues that human beings are more likely to have a reaction that is deeply tied to our emotions and less so to our reasoning. The psychologist further explains that evolution may have “hardwired” this type of moral intuition into our brains. Research has supported this sentiment. In an unpublished study, Haidt and colleagues (2000) found that participants are more likely to respond in a morally intuitive way than they are to use moral reasoning to come to a conclusion. Participants were asked to judge a male and female pair of siblings who decided to have sex while on vacation. Most participants react to the story negatively, chastising the siblings. When asked to elaborate, most participants will cite the dangers of producing incestuous offspring and how incest can damage families. When this scenario is presented in such a manner so that the siblings use contraceptives and that the incest remains a one-time event that does not damage the family, participants still find issue with the scenario. This phenomenon is further elaborated in Haidt (2001), which outlined how most people have an emotional, intuitive reaction to things and then later try to rationalize their judgments. This is in direct contrast to most moral reasoning models, which claim that people have an intuition and then reason about their intuition before they come to a judgment. In Haidt’s (2001) updated model, he claims that people intuit a judgment and only reason after they have come to their conclusion.

Similar to this way of thinking, the psychologist in *The Trolley Problem* indicates that most people will have an emotional, intuitive reaction to reach their conclusion on how to judge Daphne Jones, the woman who pulled the switch. Thomas Cathcart indicates that while this may be true, this is not necessarily right and would be considered

committing the *naturalistic fallacy* (i.e., when someone commits the error of assuming that because something is natural, it must be right). Specifically, while it may be true that people often intuit a judgment, to say that this judgment is valid because it is an intuition would be committing the naturalistic fallacy.

One of the goals of Thomas Cathcart is to expound upon the positive virtues of moral reasoning and philosophy. Near the end of the book, Cathcart (2013) argues in favor of moral reasoning by bringing up social issues like gay marriage. Before gay marriage was legalized in the United States, many people would intuit that marriage was between a man and a woman, and it was only through rigorous debate and discussion of ethics that we came to change marriage laws in the United States. As Cathcart puts it, one side was able to philosophize better than the other. So, although humans may have a moral intuition that they rely heavily upon, humans can also reason and critically think about an issue to alter their judgment. This sentiment is of particular interest to psychologists who may be interested in judgment, decision-making, and moral reasoning.

Another goal of *The Trolley Problem* is to explain the merits of discussing thought experiments like the titular scenario. Although the trolley problem itself may not be the most ecologically valid situation, it has the potential to reveal multiple facets of human thought and reasoning. In other words, humans are rarely faced with situations as dire and with such clear consequences as the trolley problem, but it can reveal what someone values. Cathcart (2013) writes that while these topics may not be the most realistic, but what they do accomplish is opening up avenues for discussion that could potentially expand our understanding of moral issues.

What Others Think

Reviews from popular periodicals have praised *The Trolley Problem* for its clarity and the light-hearted (but not oversimplified) manner in which it is presented (Akst 2013; Bakewell 2013). While some have criticized the book for the cumbersome cover story of the trial (Bakewell 2013), reviewers

have focused on the efforts of Thomas Cathcart to simultaneously give an introduction to moral philosophy and present a classic thought experiment, and to write about philosophy in such an accessible fashion (Akst 2013).

Conclusion

The Trolley Problem is an excellent introduction to the nominal moral conundrum. Cathcart presents it in both its historical context and outlines the modern versions that continue to push the bounds on moral reasoning. Even though numerous perspectives are proposed as to whether or not someone would condone pulling the switch, this is not a question where there is a truly correct answer. Thomas Cathcart's (2013) exploration is an extensive and succinct account of the trolley problem that helps to explore the moral reasoning that philosophers have discussed throughout the history.

Definition

The trolley problem is a moral thought experiment involving a trolley on course to kill some number of people. The trolley can be redirected or stopped with varying consequences and with a known benefit depending on the variation of the problem itself.

Introduction

The trolley problem is a moral dilemma used first by philosophers starting in 1967 and then adopted by psychologists to examine moral thinking in humans (Cathcart 2013). The original problem was made by Philippa Foot in a philosophical paper about abortion and the doctrine of the double effect. The problem was presented as multiple variations of a scenario in which someone had to make a choice of killing one to save five. The template scenario involved flipping a switch to change the tram to a different track. These scenarios were intended to enact the doctrine of the double effect, where good consequences with bad side effects are approvable as long as the bad side effects were not intended (1967). The original trolley problem is stated as such:

...To make the parallel as close as possible it may rather be supposed that he is the driver of a runaway tram which he can only steer from one narrow track on to another; five men are working on one track and one man on the other; anyone on the track he enters is bound to be killed. . . (Foot 1967)

The Trolley Problem in Research and Variations

There are many variations of the trolley problem that change single or multiple aspects of the dilemma. The two most common variations are the “loop variant” and “fat man variant.” The loop variation remains similar to the original problem as stated by Philippa Foot, where the participant is given the option to either allow the trolley to continue on its current path which will kill five people or pull a lever redirecting the trolley onto a track which has one person on the track. Whereas the fat man variation usually does not involve a lever, but instead a fat man or large man with a backpack. The fat man variation is generally stated as such:

You are standing near a trolley track, there is a trolley heading down the track toward five workers who are unaware of the trolley and whom will die if nothing is done. There is a fat man next to you, large enough to stop the trolley if pushed onto the tracks; this will kill the fat man. Do you stop the trolley by pushing the fat man onto the tracks or let the trolley hit the five workers on the track? (Cathcart 2013)

These two variations have the same outcome, but drastically different responses, which change further when details about the problem or participants are altered, for example, by adding descriptions of the possible victims of the trolley (Bleske-Rechek et al. 2010) and when participants are psychopaths/sociopaths (Greene 2013). Participants of the basic lever problem will generally choose to pull the lever, whereas in the fat man problem, they do nothing. This is most likely due to spacial and social reasoning, in that pulling a lever to kill one and save five physically separates the participant from the death of the one. In the fat man problem, however, the physical action of pushing a man to his death, even to save five, is associated with murder (Greene 2013).

Bleske-Rechek et al. (2010) at the University of Wisconsin investigated the trolley problem using different descriptions of the man on the looped track. They tested this by replacing the man in the loop variant with relatives of varying genetic relatedness (0–0.5), people of varying ages (2–70), and people of reproductive

opportunities or current mates. They found that when younger, more related people or mates were standing next to the participant in the scenario, the hypothetical person was less likely to be sacrificed for the five (Bleske-Rechek et al. 2010). Results matched inclusive fitness theory; people will prioritize saving themselves, genetic relatives, the young, and potential or current mates over anyone else, even if saving the one relative, kid, or potential mate means allowing five people to die. This evidence, according to Bleske-Rechek et al. (2010), suggests that human moral thinking is deeply seated in our evolutionary history. However, some researchers disagree that hypothetical situations are enough to trigger evolved mechanisms (discussed in Bleske-Rechek et al. 2010).

Another study by Navarrete et al. (2012) used virtual reality headsets with audio to test a realistic example of the trolley problem. In this study, participants were allowed to acclimate to the headset and controls. Participants were positioned on a virtual bridge near the track in a steep ravine and were told that a runaway train car was quickly rolling down the tracks. They are also told that people often use the tracks as a way of travel and due to the nature of the ravine that they will not be able to see or hear the train car until it is too late. From this point, the participant can see, and shortly after hear, the train car barreling down the track. Around the same time, five animated white men begin walking on the main track and one white man begins walking on the track. If participants did not act, the five white men were run down (accompanied by loud screams). However, those who pulled the lever to switch the train car onto a side track killed only one person. Approximately 89.5% of participants chose a utilitarian response, killing the one. Similarly, in his book *Moral Tribes*, Greene (2013) takes an in-depth evolutionary approach to the trolley problem and its variations. He shows that only 20% of people are willing to push a man onto the tracks to save the five workmen. Nevertheless, over 80% of people were willing to switch the trolley onto the second track with one person. Pushing the man with a backpack or the fat man saves the most lives, but people have a negative emotional reaction to this choice. When there is an

option to pull a lever and switch the train onto other tracks, this negative emotional response is weakened (Greene 2013). Greene argues (see also Singer 2005) that pushing the man onto the track is a personally direct action, whereas pulling a lever is an indirect and distant action, and this pushing that man is more distressing than pulling the lever. Greene (2013) provided support for his hypothesis by administering the trolley problem to psychopaths/sociopaths, who showed considerably less variance when choosing to sacrifice the man to save the five (i.e., demonstrated less empathy by tending to logically choose to sacrifice the one and save the five regardless of the circumstances).

Cross-Cultural Trolley Problem

A study by Gold et al. (2014) examined the trolley problem cross-culturally using a real-life example based off the trolley problem that involved orphans and food. The study comprised 45 British participants (24 women), 61 Chinese participants (54 women), and 63 other international participants (i.e., “foreigners,” 46 women). A slightly altered trolley problem was given that involved an 18-s animation of a large ball rolling toward a group of five orphans. They were given the option to flip a switch in order to redirect the ball toward a single orphan, but instead of the children dying as per the original problem, they would simply not be given a meal if run over by the ball. They found that 80% of British participants and 69.35% of the foreigners flipped the switch, denying the one orphan a meal instead of five, whereas only 49.18% of Chinese participants flipped the switch (Gold et al. 2014). Similar research has also found that 76.36% of British participants and 64.44% of Chinese participants (who rated similarly on measures of moral judgments) flipped the switch to save five orphans from the trolley and sacrifice one when using the original problem, with both sets of participants mostly citing utilitarian reasoning (e.g., “the greater good”) for why they flipped the switch (Gold et al. 2014). As for participants who did not flip the switch in either the orphan meal variation or original trolley problem,

the British participants generally voiced that they did not want the responsibility of deciding someone’s fate, whereas Chinese participants similarly claimed they did not want to alter destiny/fate (Gold et al. 2014). More specifically, British participants who did not pull the switch either felt a strong negative emotional response to the idea of either killing the one man or not feeding the one child. For the Chinese participants, however, they felt pulling the switch was not their responsibility to begin with (i.e., pulling the switch was outside their control). Therefore, differences in results can possibly be contributed to cultural beliefs or upbringings (Gold et al. 2014).

Conclusion

The trolley problem can and has been used to analyze moral thinking from an evolutionary perspective in humans. Since the original problem was proposed by Foot, many variations of the trolley problem have spawned. The overall problem can be used in research to test moral thinking in humans from an evolutionary or more generally social perspective. In the loop variation where participants may pull a lever to redirect the trolley onto a second track to kill one person and save five, 80% or more of participants tend to logically save the majority, unless the one being killed is a genetic relative, child, or mate (Bleske-Rechek et al. 2010). In the fat man variation where participants are given the option to push or drop a fat man onto the tracks to save five from the trolley, only 20% or fewer participants choose to sacrifice one person to save many, with the exception of those low in empathy (i.e., psychopaths/sociopaths; Greene 2013). Results support evolutionary theories of moral reasoning (see, e.g., Bleske-Rechek et al. 2010) and provide important insight into human social behavior in general.

Comparing similarity of identical and nonidentical twin pairs to estimate genetic and environmental influence on trait variation.

Introduction

Twin studies allow researchers to investigate the nature versus nurture question: are our individual characteristics due to genes or upbringing? Twin studies have long contributed to psychological science, but have only recently been applied to evolutionary psychological questions.

The classical twin design is basically a natural experiment: twins pairs are born either genetically identical (sharing all their genes), or nonidentical (sharing on average half of their segregating

genes, like normal siblings). If a trait is more similar among identical twin pairs than among nonidentical twin pairs, it can be inferred that the trait is influenced by genetic factors.

Quantifying Genetic and Environmental Influences on Trait Variation and Covariation

Inferring a genetic influence on a trait does not imply that other factors do not also play a role – invariably they do. Structural equation modelling can be used to estimate the proportion of a trait's variation that can be explained by genetic factors, aspects of the environment that twins share (e.g., early home environment), and residual factors (e.g., idiosyncratic experiences, random biological effects, and measurement error). This partitioning is possible because these different sources of variation predict different patterns of twin correlations. If genetic factors were the only source of trait variation, we would expect a twin correlation of 1 for identical pairs and 0.5 for nonidentical pairs, in line with their respective genetic similarities. If shared environment were the only source of variance in a trait, we would expect a twin correlation of 1 for both identical and nonidentical pairs, since both fully share the shared environment, by definition. Residual factors are uncorrelated in both identical and nonidentical pairs, by definition, so if they were the only source of variance we would expect both identical and nonidentical twins to be uncorrelated. Maximum likelihood structural equation modelling estimates the combination of genetic, shared environmental, and residual influences that best matches the observed twin pair correlations. Statistical confidence intervals around the estimates can be calculated, and age and sex effects can be estimated and controlled for.

These methods lend themselves to multivariate extension as well. Analysing two or more traits together enables estimating the relative contribution of genetic and other influences to correlation *between* traits as well as to variation in each individual trait. For example, the genetic correlation

between two traits can be estimated – an index of the extent to which the genetic influence on two traits overlaps.

The reader can find in-depth treatments of the methods and assumptions underlying the classical twin design elsewhere. Neale and Maes (2004) provide a comprehensive book-length treatment, Posthuma et al. (2003) provide a good overview journal article format, and Verweij et al. (2012a) provide step-by-step demonstration of heritability estimation in OpenMx, a popular program for analysing twin data.

Twin Studies and Evolutionary Psychology

Evolutionary psychology and behavioural genetics two fields that developed largely in isolation from each other. Their separation was due in part to the fundamentally different focus of each field. Behavioural genetics focuses only on differences between individuals, while evolutionary psychology has traditionally focussed on characteristics universal to all humans or all men/women. However, the subjects of the two fields are integral to each other: genetic variation in traits allows them to evolve, and evolution shapes the structure of genetic variation and covariation in traits. As such, in the last decade the fields have begun to integrate (Zietsch et al. 2015a).

A simple and profound message for evolutionary psychology in the findings of twins studies is that, for almost all human traits, individual differences are in large part due to genetic differences between people (on average accounting for 50 % of the total variance) and not due to differences in their upbringing (on average accounting for 0 % of total variance) (Polderman et al. 2015). This principle contrasts with a conventional wisdom of evolutionary psychology: that important behavioral characteristics will be fairly universal at the genetic level (i.e., exhibit low or zero heritability). Many evolutionary psychological theories are based on the premise that individual differences are caused by universal psychological mechanisms that calibrate traits to aspects of the early environment or other aspects of the individual.

These theories are often incompatible with the findings of twin studies (Zietsch 2016).

Given the pervasive genetic variation in human behavioral traits, a goal of evolutionary psychology should be to understand the evolutionary basis of this variation. Such widespread genetic variation is a conundrum, central to evolutionary biology as well, because natural selection normally winnows away genetic variation, favouring only the optimal genotype. Twin studies provide an avenue for addressing this problem.

A striking example of the conundrum is the Darwinian paradox of homosexuality. Twin studies have shown a substantial genetic basis to variation in sexual orientation, so the question is: how are the genes predisposing to homosexuality maintained in the population when homosexuality reduces reproductive success? A twin study by Zietsch et al. (2008) provided a potential answer. It showed evidence suggesting that the genes predisposing to homosexuality *increase* the mating success of heterosexual carriers of those genes. This mechanism for maintaining genetic variation in a population is called *antagonistic pleiotropy* – meaning that the same genes have multiple effects (pleiotropy) with opposite (antagonistic) consequences for fitness.

Another example of the genetic variation conundrum is the wide variation in women's preference for facial masculinity in a partner. The dominant evolutionary psychological theory explaining this variation has been that universal psychological mechanisms calibrate women's facial masculinity preference to aspects of the environment or to their own characteristics (such as attractiveness). However, Zietsch et al. (2015b) showed that these putative calibration effects were tiny (accounting for less than 1 % of variation in the preference), whereas genetic factors accounted for around 40 % of the variation. Lee et al. (2014) provide a clue to why this genetic variation may be maintained in the population: they showed that the genes that increase facial masculinity in males also decrease the attractiveness of female relatives. Therefore, even if there is a genetic advantage in choosing a masculine-faced father for male offspring, such a choice may be disadvantageous for female offspring, potentially neutralising the fitness

consequences of women's preferences for masculine or feminine faces.

A final example of the genetic variation conundrum can be seen in personality traits, which have been shown by twin studies to be substantially heritable (Polderman et al. 2015). Again the question is why this genetic variation persists. Using results from twin studies, along with new genome-based methods, Verweij et al. (2012b) showed that the genetic variants underlying personality traits are likely to be low-frequency and directionally dominant (i.e., dominant or recessive in a biased direction with respect to fitness). Given prior evolutionary-genetic modelling, these findings suggest that genetic variation is maintained by a balance between selection on the one hand and accumulation of random mutations on the other (i.e., *mutation-selection balance*).

Conclusions

Twin studies are powerful tools for investigating the genetic and environmental sources of human individual differences. Decades of twin research have shown that virtually all traits exhibit substantial genetic variation, whereas upbringing contributes surprisingly little. Recent and future twin studies can advance the important goal of understanding the evolutionary basis of this genetic variation.

Synonyms

Cohabitation; Father presence; Intact families; Same-gender parents; Stepfamilies

Definition

Families in which offspring receive direct care, support (financial, emotional), and/or other resources (e.g., energetic, social) from two co-residential parents or caregivers.

Introduction

In the United States, it is becoming increasingly common for children to be reared outside of what was once viewed as the “traditional” family context: co-residence with the biological parents (e.g., Fedewa et al. 2015; Hemovich et al. 2011). Understanding the consequences of rearing children within a variety of family structures is of interest to social scientists across disciplines. Here, we consider average differences in children’s outcomes across two- and single-parent families; intervening factors that contribute to these average differences (where they exist); and variation in parental behavior and children’s health and well-being within two-parent families.

Two-Parent Versus Single-Parent Families

There is a widespread belief that growing up in a two-parent family is preferable to growing up with a single parent. The empirical literature across psychology, sociology, and family studies is replete with research documenting average differences between children reared across these dichotomized contexts. The narrative that has emerged is that children and adolescents reared in stably intact families with their biological mother and father are more socially competent, achieve more academically, and enjoy better physical and mental health compared to youth reared in biologically divorced, separated, or single-parent families (e.g., Geary 2007; Hemovich et al. 2011; McLanahan et al. 2013). There is some evidence that these disparities become more pronounced when the parental divorce or separation occurs early in a child’s life (McLanahan et al. 2013).

Due to men's paternity uncertainty and lower minimum obligatory investment in reproduction compared to women, paternal investment is more sensitive to socioecological factors, and thus more variable in quantity and quality, than maternal investment (Geary 2007). These conditions render biological father absence statistically more prevalent than biological mother absence. In this context, the focal comparison in many studies of family structure is between children reared in intact, two-parent families and those reared by single mothers. Though less common, research also documents developmental challenges related to growing up without one's mother or in a single-father (versus two-parent) home (e.g., substance use; Hemovich et al. 2011). The apparent advantages of dual parenting have been observed regardless of parent gender, with children reared by same-gender parents (two mothers or two fathers) enjoying cognitive outcomes, peer relationships, and mental health that are comparable (or, in some cases, superior) to peers reared by biological parents of different genders (e.g., Fedewa et al. 2015).

A variety of explanations have been offered for the average differences in child outcomes across two-parent and single-parent families, including (but not limited to) differences in income, parental monitoring, and parent-child relationship quality (e.g., Hemovich et al. 2011). From a functional perspective, psychosocial stress that accompanies parental dissolution may guide children toward developmental and behavioral pathways that promote fitness under stressful-unsupportive versus benign-supportive conditions. On this view, for instance, daughters who experience father absence are posited to demonstrate early and short-term sexual behavior to prepare for environments in which male investment in partners and offspring is relatively low (Draper and Harpending 1982). Others note that observed relationships of this kind (e.g., between family environments and children's development) are influenced by shared genetics, as absent fathers may be more likely to transmit genes for impulsivity and risk taking to their children than are fathers who remain present (e.g., Schlomer et al. 2018).

Social scientists have taken deliberate steps in an attempt to examine potential causal influences of

father-absent family structures while accounting for environmental and genetic confounds. McLanahan et al. (2013) reviewed studies that implemented causally informed research designs (e.g., longitudinal studies, natural experiments) to test for effects of father absence on children's outcomes across the life course. They found that when rigorous designs were implemented, father absence (versus presence) predicted lower high school graduation rates, increased externalizing problems and substance use, and worse mental health as adults. (However, the effect sizes documented in these studies were generally smaller than those obtained using cross-sectional designs.) Others have begun to explore the possibility that outcomes often considered as resulting from family structure reflect interactions between genetic risk factors and environmental exposures to father-absent environments (e.g., Schlomer et al. 2018).

Variation in Parental Identity and Quality of Investment

Whether observed relationships between family structure and children's outcomes are viewed through the lens of conditional adaptation, shared genetics, or socially transmitted dysfunction, the "effects" of being reared in two- versus one-parent families undoubtedly are more complex than average differences between children reared in such families might suggest. Although the experiences of children growing up in single- versus two-parent homes may be qualitatively different, the effects of different family structures (and the purported benefits of living in two-parent families) may depend on which parents are present in the home, their relationship with each other, and what these parents do while they are present (i.e., the quality of their behavior). In other words, children's outcomes are likely to reflect the fact that not all two-parent family contexts are equivalent.

Stepparent families (two-parent families in which a child is reared by one biological and one non-biological parent) have earned an overall negative reputation across diverse empirical literatures. Children residing in stepfamily households demonstrate reduced academic achievement,

psychological well-being, and social competencies compared to children residing in intact biological families (reviewed in Amato and Sobolewski 2004). Children reared by cohabiting (but unmarried) biological parents often exhibit outcomes that are comparable to children reared within stepfamilies (Brown 2004). Further, children living with one biological and one non-biological parent, whether married or unmarried, are more likely to experience multiple forms of victimization (e.g., maltreatment, physical or sexual abuse) relative to children living with two biological or adoptive parents (Turner et al. 2013).

These baseline disparities between children reared in biologically intact versus stepparent or cohabiting families may be driven in part by differences in the quality of family relationships across these contexts. Interactions within stepfamily structures are more discordant than those within biologically intact families, and children in these families experience greater exposure to parental conflict, substance abuse, and psychiatric disorders (e.g., McLanahan et al. 2013; Turner et al. 2013). The relationships between parents and their stepchildren also are qualitatively different than those between parents and their biological children. Stepfathers, specifically, spend less time with and are less emotionally close to their stepchildren than are co-resident biological fathers (Amato and Sobolewski 2004). However, when children and stepparents are able to develop close bonds, children do seem to benefit from the presence of the second parent (Amato and Sobolewski 2004).

Variation in the quality of parenting provided by the biological parents also has a powerful influence on children. DelPriore et al. (2017) tested for the effects of father-daughter relationship quality on daughters' risky sexual behavior and related outcomes between and within families. The results suggested that daughters who had high-quality (warm, supportive) relationships with their fathers while growing up received more parental monitoring, were less likely to affiliate with sexually promiscuous peers, and engaged in less risky sexual behavior during adolescence compared to daughters who reported lower-quality relationships with their fathers. Further, in a study by Jaffee et al.

(2003), the prolonged presence of fathers who engaged in high amounts of antisocial (e.g., illegal, aggressive, and impulsive) behavior predicted increases in children's conduct problems. In such this case, the two-parent family structure may do more harm than good, conferring upon children both genes and environments that encourage socially undesirable behavior. Although consistently higher (and often less variable) than paternal care, quality of maternal care also matters for children. Goodman et al. (2011) conducted a meta-analysis exploring possible effects of maternal depression. They found that children living with a depressed mother exhibited higher rates of emotional and behavioral issues (e.g., anxiety, aggression) throughout childhood compared to children residing with mothers who did not meet criteria for a depressive disorder. This relationship was strongest for young children, suggesting a decline in sensitivity to maternal quality in later adolescence.

Conclusion

Growing up in a stably intact family, whether with different- or same-sex parents, forecasts a number of socially desirable outcomes for children and youth. However, simply being reared in a two-parent family is not sufficient to guarantee children's health and well-being. The benefits of co-residing with two parents often depend on the nature of the relationship between the parents and the quality of caregiving provided. To the extent that marital relationships that remain intact are characterized by high-quality (warm, supportive, low-conflict) relationships between parents and their children, one might expect that these families will allow most children to reach their potential. Children's genes and environments may collaborate to foster health and well-being in such contexts. However, to the extent that living in a two-parent family keeps children in close proximity to a biological parent or stepparent who is emotionally cold or violent, who abuses drugs or alcohol, or who suffers from other mental health issues, the benefits of dual parenting may be overstated.

Types of Crying

Guy Madison¹ and Edward Dutton²

¹Umeå University, Umeå, Sweden

²Ulster Institute for Social Research, London, UK

Synonyms

[Crying diversity](#); [Crying versatility](#)

Definition

Qualitatively different forms of weeping and/or shedding tears.

The range of expressions of emotion associated with shedding of tears from the eyes.

Introduction

Crying is generally understood as shedding tears in response to some emotional state or reaction, more specifically known as weeping. Relevant terms are bawling, blubbering, moaning, sniveling, sobbing, tearing, wailing, weeping, and whimpering, as well as tremor, convulsions, irregular and interrupted breathing, specific facial expressions, and the “lump in the throat” sensation. Accordingly, weeping is often accompanied by vocal emissions, as the term crying implies. Here, we list different types of behaviors that are subsumed under the rubric of emotional crying

and attempt to provide a brief description of their use and etiology. The alternative is reflexive crying, which is defined either as crying because someone else is crying (reviewed in Eisenberg and Lennon 1983, pp. 105–107) or as a response to wind, cold, smoke, and other chemical and physical irritants (Bindra 1972; Bellieni 2017). The latter type of reflexive crying allows the eye to wash away the objects or toxins which have irritated it. Lacrimation is a technical term for tearing as such.

Watery Eyes

Even a small excess of lacrimal fluid may be visible from a few meters' distance, providing a signal of emotional upset. The receiver of this signal typically reflects on her role in the emotional reaction, prompting a change in her behavior, such as apologizing, backing off, withdrawing, or comforting the crier (Hendriks et al. 2008; for a review, see Miceli and Castelfranchi 2003). It has been suggested that blurring the vision with tears handicaps aggressive action and thus serves as a signal of submission, or that it is a way of expressing helplessness and so eliciting an altruistic response (Williams and Morris 1996). Across two measurements in 1981 and 1996, more than half of all crying events for males fitted the description "red eyes and a tear or two" but only one third of events for females, while sobbing, shaking, and bawling constituted more than half of all crying events for females but only one sixth for males (Lombardo et al. 2001). Likewise, 71% of males' crying episodes featured watery eyes, but only about half of females' episodes, according to a diary study (Frey et al. 1983).

Flowing Tears and Facial Expressions

This is where the excess leads to tears running down the cheek, which can occur both in isolation and with any range of additional behaviors. These include a particular set of facial expressions. The corrugator supercilii muscles narrow the eyebrows and wrinkles the forehead, which is

commonly accompanied by grimacing due to excitations of several facial muscle groups, particularly in the cheeks and chin, including, for example, a lowered and extended lower lip. These specific "crying faces" have not been systematically studied, although they might have significant communicative features.

Vocal Emissions

Crying is sometimes associated with extremely strong emotions of despair, a despondent state in which the person seems oblivious to the external world and has no or little control over her behavior. From this end of the spectrum to silent flowing tears, there may be, in decreasing order of intensity, bawling, moaning, and wailing, as might also be reactions to physical pain, followed by whimpering and snivelling, which is characterized by vocal emissions of moderate loudness, often combined with sounds produced by airflow through fluid in the nasal cavity. Blubbering and sobbing are mainly characterized by sounds produced by airflow through the respiratory passage, more specifically convulsive inhaling and exhaling, but may also include softer vocal sounds. Sobbing is specifically related to the irregular and interrupted breathing that is typical of more intense crying and which constitutes around 10–15 percent of all crying episodes (Frey et al. 1983). This proportion may be substantially larger in females (Lombardo et al. 2001). Convulsions and tremors may furthermore be extended to the whole body, including writhing and kicking.

Tears of Sadness and Pain

Sorrow is the archetypical cause of crying, the type of which tends to be long-lasting, difficult to stop once commenced, and to preclude the crier from any other activity. It strongly impacts the crier, but to a lesser extent those who might observe the crier. Such crying can last from a few minutes to several hours, in which case it tends to wax and wane over the longer intervals (Bindra 1972; Williams and Morris 1996). It is associated with extremely negative situations

such as the loss or threat of loss of a loved one, severe personal failures, or self-pity. When caused by physical pain, crying is more rhythmic. There has been considerable speculation that crying in these situations has beneficial effects, in accord with ancient notions to that end in folk psychology (Bylsma et al. 2008), and entails some sort of positive effect or catharsis (for reviews, see Rottenberg et al. 2008a; Stougie et al. 2004). It has been proposed that the relatively rhythmic nature as well as the soothing effect of the tears on the cheeks may serve to calm the crier down (Bellieni 2017).

Tears of Need

Rhythmic crying is generally heard from hungry babies, which mothers will do almost anything to placate. This kind of crying seems clearly to serve an adaptive function to elicit assistance, as the hearer is desperate to stop it, and has been suggested to directly increase maternal milk supply, through the so-called milk let down reflex (Zeifman 2001). It has also been speculated that this effect is so strong that it can be counterproductive under conditions of excessive crying, such as colic, or when the child otherwise remains unsatisfied, in which case it may suffer abuse and even death at the hands of its caretakers (Barr 1990). In adults, hunger, cold, and other threatening states may also elicit crying, even to the extent of “fake crying” (Vingerhoets et al. 2016). As noted above, crying may similarly have evolved in order to signal submission to an aggressor as well as to stabilize the mood of the crier via the release of stress hormones, evoked by a feeling of loss of control. In most people, crying of a similar kind can be evoked empathetically, at the sight of the suffering of another or at the sight of their sadness, though this will be qualitatively different again and will tend to involve tears without actual crying.

Tears of Joy

It may seem contradictory that a considerable proportion of crying episodes is associated with

positive emotions (Bylsma et al. 2008). Typical elicitors of tears of joy are empathy (Rottenberg et al. 2008b), elation (Bindra 1972), and pathos (Lombardo et al. 2001), all of which may reasonably be associated with pride, in-group favoritism, and rites of passage. Even funerals may fit this pattern, as the ceremony expands upon the character, virtues, and achievements of the deceased, which naturally extends to some extent to the relatives and friends present. Other typical examples include weddings, when children receive their exam results, and other manifestations of accomplishment, such as experiencing profound artistic works. For example, weeping and “chills” are frequently experienced when listening to some kinds of music (Gabrielsson 2011; Sloboda and O'Neill 2001).

Conclusions

There is much theorizing on the types of crying, and it has been suggested that different evolutionary explanations apply for qualitatively different kinds of crying (Efran and Spangler 1979; Vingerhoets et al. 2001). Indeed, it has been found that there are consistent sets of circumstances, such as the death of a loved one, in which people cry due to sadness, just as there are consistent sets of circumstances in which people will cry due to joy, such as the wedding of one to whom one is close. It has been proposed that this kind of crying results from the way in which overwhelmingly positive feelings interfere with the body's epistasis, meaning that something has to be done in order to stabilize the body. Crying may achieve this by releasing hormones that bring the person down toward a manageable level of joy (Bellieni, 2017). Consistent with the idea that crying constitutes loss of control, people are most likely to cry alone and then decreasingly likely to cry in front of people the less close they feel to them, presumably because crying evinces their vulnerability to an emotional loss of control. There may also be a broader group dimension to crying in front of others, both to positive and negative events. If it is evoked publically, including at the clichéd funeral and wedding, it can be

seen as signalling empathy and selflessness and would thus be of adaptive value.

Definition

According to Smuts and Smuts (1993), sexual coercion concerns the use, or threat of use of force, increasing the chances the targeted female will mate with the attacking male. Alternatively, sexual coercion also decreases the likelihood the female will copulate with other males. In both

instances, the female experiences significant fitness costs due to the sexual male's aggression.

Introduction

Although males and females are known to align their reproductive interest (as predicted by sexual selection theory), it is not uncommon for one sex to attempt to increase its fitness at the expense of the other (i.e., sexual conflict). The incompatibility in fitness goals is facilitated by the asymmetry observed in parental investment (Trivers 1972). Resource availability limits the reproductive success of females, whereas the number of reproductively available females restricts males' fitness (Muller et al. 2009a). Therefore, males invest more in mating effort, seeking multiple sexual partners, and fending off rivals rather than allocating resources to parental effort. Since females accrue most of the costs associated with reproduction, females tend to be more selective when relative to males choosing a mate. Female mate bias, however, is not only reflected in their degree of preference for males displaying a particular trait. Resistance against the advances of males exhibiting unattractive characteristics (Watson-Capps 2009) also exemplifies the cognitive and behavioral mechanisms females employ to protect their reproductive interests. Female preference selects in favor of a trait, while resistance selects against it (Watson-Capps 2009). These socio-ecological forces generate higher reproductive variance in males than in females.

Consequently, unattractive males may use force or threat of force to overcome the female's resistance, increasing the probability the targeted female will mate with the aggressor. Sexual coercion is thus a subcategory of sexual conflict (Watson-Capps 2009). Depending on the nature of the interaction, sexual coercion can be further subdivided into direct and indirect.

Direct Sexual Coercion

Direct sexual coercion refers to the employment of force destined to increase the likelihood a male will mate with a female despite the female's

resistance (Muller et al. 2009a). The literature classifies direct sexual coercion into intimidation, harassment, and forced copulations. Harassment involves the male's mating insistence despite the female's refusal. The repetitive nature of the behavior eventually leads to the female's submission. Intimidation, alternatively, describes instances in which the male will attack the refusing female, as a form of retribution, increasing the female's acceptance toward the male's advances (Muller et al. 2009a). Finally, forced copulation refers to the male's aggressively restraining the female, leading to an imminent mount (Clutton-Brock and Parker 1995; Muller et al. 2009a). Some authors also consider infanticide, the elimination of infants with the aim of increasing the chances the targeted mother will mate with the attacker, as another manifestation of sexual coercion (Watson-Capps 2009).

Intimidation occurs in several primate species. For example, chimpanzee males will attack females to facilitate the establishment of a sexual consortship (Clutton-Brock and Parker 1995). Even though most of the times, aggression against female chimpanzees transpires in the absence of any clear behavioral or physiological immediate cue (e.g., the targeted female did not exhibit a sexual swelling; Clutton-Brock and Parker 1995), it is not uncommon for the victim to copulate with the aggressor (Clutton-Brock and Parker 1995). In Japanese macaques (*Macaca fuscata*), females who are frequently the target of aggression are also more likely to mate with the aggressors rather than with less aggressive males (Clutton-Brock and Parker 1995).

Harassment is found across various taxa. For example, in fallow deer (*Dama dama*), males chase and insistently try to copulate with females (Clutton-Brock and Parker 1995). Similarly, due to the considerable sexual dimorphism in elephant seals (*Mirounga angustirostris*), male's mating attempts leads to female injury (Clutton-Brock and Parker 1995). In avian species, female ducks face the risk of drowning due to male intrasexual competition (Clutton-Brock and Parker 1995). In nonhuman primates, such as chimpanzees it is not uncommon for males to employ harassment to increase the likelihood of future copulations (Muller et al. 2009b).

Although forced copulations occur in several vertebrate and invertebrate species (Clutton-Brock and Parker 1995; McKinney and Evarts 1998), relative to other forms of sexual coercion, this particular sexual coercion is less prevalent in nonhumans primates. For example, male mountain gorillas (*Gorilla beringei*), and male chimpanzees (*Pan troglodytes*) rarely restraint females during mating (Muller et al. 2009b; Robbins 2009). Orangutans' (*Pongo pygmaeus*) behavior, however, stands in contrast to this general pattern. It is worth noting that even though initial primatological reports suggested unflanged males, that is, small individuals lacking cheek flanges, employed forced copulations, current evidence indicates that this behavior is part of a general mating strategy of male orangutans (Knott 2009). The female's resistance is dependent on the time of the mating during the estrous cycle. Females reject flanged males if the copulation attempt occurs when the female is not ovulating, as well as unflanged males if they seek to mate during the ovulatory stage (Knott 2009). As a tactic destined to confuse paternity, and decrease the risk of infanticide, females do copulate with unattractive males outside of the ovulatory days (Knott 2009).

Indirect Sexual Coercion

Also conceptualized as coercive mate guarding (Muller et al. 2009a), indirect sexual coercion decreases the likelihood the female will mate with another male (Muller et al. 2009a). Herding, sequestration, and punishment are the main subclasses of indirect sexual coercion. Concerning herding, the guarding male uses aggression to separate the female from competing males. This strategy restores the physical proximity between the guarding male and the female (Muller et al. 2009a). Sequestration occurs when the male uses force to separate the female from the core group, decreasing the likelihood the female will mate with other males, for example, before or during ovulation (Muller et al. 2009a). Punishment is defined as the male's aggression against a female due to her association or mating with other males. This expression of coercive mate guarding,

decreases the risk the female's behavior will repeat in the future (Muller et al. 2009a). Dominant males employ punishment to decrease the risk of females copulating with other males. High-ranking male chimpanzees, for example, target females who associate with other males (Muller et al. 2009b). After a takeover, male hamadryas baboons (*Papio hamadryas*) employ neck bites, nonlethal aggression directed at the nape of the female's neck, to increase the level of female submission. Females experience lower rates of aggression if they are physically close to the male and spend time grooming him (Swedell and Schreier 2009).

Species living in fission–fusion societies, where females spend time alone, are especially vulnerable to herding. In bottlenose dolphins (*Tursiops truncatus*), males are known to form nested alliances restricting the female's free movement (Connor and Vollmer 2009). Primate species living under a fission–fusion structure, such as chimpanzees, also employ herding as part of the establishment of consortships with fertile females (Muller et al. 2009b). Herding in chimpanzees and bottlenose dolphins is suspected to be the product of convergent evolution in life history traits, and social complexity. Both species exhibit slow life history traits and large brain size. Elements necessary for the maintenance of sophisticated political lives include males developing coalitions and alliances, which can be used to coerce females (Connor and Vollmer 2009). Although males of various mammalian species use sequestration, such as in bottlenose dolphins (Connor and Vollmer 2009), in nonhuman primates, this strategy is limited to a few taxa including chimpanzees and Hamadryas baboons (Muller et al. 2009a).

Sexual Coercion in Humans

The plasticity and flexibility of human mating strategies are also evident in the presence of different expressions of sexual coercion. Concerning direct sexual coercion, several studies had found evidence of harassment, intimidation, and forced copulations (Camilleri and Quinsey 2012). Similarly, indicators of indirect sexual coercion, such as sequestration, herding, and punishment are also

reported across human societies (Camilleri and Quinsey 2012). Intimate partner violence (and interpersonal aggression generally) is often divided into several highly intercorrelated categories (Figueredo et al. 2018): (1) verbal/psychological; (2) physical; (3) escalated/life-threatening; and (4) sexual. They have nevertheless been repeatedly shown to represent convergent indicators of a single latent construct (Figueredo and McCloskey 1993; McCloskey et al. 1995). As such, it is probably better to think of these categories as taxonomies of behaviors than as taxonomies of perpetrators, as the same perpetrators are often likely to engage in several of these behaviors. It is also likely that the distribution of offenders might reflect differences in the relative severities of aggression levels represented by the categories, aligned along a continuum. Thus, offenders with a lower level of aggressiveness might only engage in verbal/psychological abuse; offenders with a somewhat higher level might engage in both verbal/psychological and physical abuse; offenders with an even higher level might engage in verbal/psychological, physical, and escalated/life-threatening abuse. It is unclear where sexual abuse would fall on this continuum, as it is so often combined with the other behaviors. Nevertheless, such a quantitative model is in need of development and validation.

Conclusion

Driven by the twin sexual selective pressures of intrasexual competition and intersexual selection, sexual coercion stands reconceptualized as a special case of sexual conflict, which occurs when the fitness interest between the sexes is unaligned. Sexual coercion is further subdivided into (1) direct coercion, wherein the male's use of force against a female increases the probability of copulation despite the female's resistance, evidenced in forced copulations, sexual intimidation, and sexual harassment; and (2) indirect sexual coercion, reflected in instances of sequestration, herding and punishment, where the male coercion functions to decrease the likelihood the female will copulate with other males.

Unconditioned Response

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

Reflexive response; Unconditional response; Unconditioned reflex

Definition

An unconditioned response is a response that is reflexive and involuntary in nature, which is reliably induced every time an organism comes across to biologically significant stimuli.

Introduction

Living organisms are naturally endowed with a variety of unconditioned responses that prepare them to interact with their environment in an adaptive and usually favorable manner (Baum 2017). Organisms do not have to learn these responses since they biologically received them. These type of responses (i.e., unconditioned responses) appear when an organism comes across stimuli which automatically, and naturally, trigger them (Thines 1987). For instance, a puff of air to an individual's eye area automatically induces a response of an eyeblink (Shanks 1995). The person has not learned to respond with an eyeblink in the presence of this stimulus (i.e., puff of air); he/she naturally and automatically exhibits this response to adapt to the environmental conditions and increases the chance to survive (Thines 1987). The responses that do not need to be learned and are exhibited naturally and automatically by living beings in reaction to a variety of biologically as well as environmentally relevant stimuli are widely known as unconditioned responses. In addition, unconditioned responses are reflexive as well as involuntary in nature and are reliably induced by unconditioned

stimuli (McSweeney and Murphy 2014). The scientific community has obtained valuable knowledge related to unconditioned responses through the outstanding work of a Russian physiologist named Ivan Petrovich Pavlov on a type of learning that is widely known as Pavlovian, classical, or respondent conditioning (Thines 1987).

The Nature of Unconditioned Responses

Natural selection has significantly influenced the development and preservation of unconditioned responses. It has been consistently proposed that unconditioned responses are significantly associated with well-being maintenance, reproduction, and survival enchantment (Baum 2017). For example, eyeblink, shiver, sneeze, and adrenaline release in threatening situations as well as sexual excitement constitute unconditioned responses that seem to be always significantly associated with the preservation and enhancement of healthiness, survival, and reproduction (Ramnero and Torneke 2011). In addition, it has been proposed that people who consistently displayed these unconditioned responses were healthier, reproduced more, and thus enjoyed enhanced survival abilities compared to the people whom unconditioned responses were weak or nonexistent (Baum 2017).

In this sense, over the breeding of multiple generations, the genotypes that promoted a consistent reflexive system would be inclined to enhance reproduction and survival in the prevailing environment more often, up until the maximal fitness is achieved. In other words, the unconditioned responses that living organisms exhibit nowadays are the product of natural selection over the course of long periods of time (Baum 2017). Yet, even though these type of responses improved and persevered fitness in the past, there is no evidence that ensures that the same type of responses would continue to help humans and other living organisms to keep improving and preserving fitness in today's environmental dynamics (Ramnero and Torneke 2011). For example, if the present environmental conditions have significantly altered from the ones that

favored the selection of these types of responses in the past, selection would be enforced to develop new behavioral responses.

Unconditioned Response and Its Role in Classical Conditioning

Ivan Petrovich Pavlov, the founder of classical conditioning through his work on the gastrointestinal system, shed light on the way that living creatures could respond to the associative bonds that are formed between unconditioned stimuli and environmental dynamics enabling them to achieve learning that enhance their capacity for adaption and survival (Ramnero and Torneke 2011). Specifically, I. P. Pavlov examined the alternations of dog's saliva and digestive fluid secretion through their mouth and stomach while feeding. Dogs have an automatic response to the sight of food, that is, they secrete saliva and digestive fluid. Dogs do not have to learn this response since they biologically received it. Yet, at some point, during the course of the experimental procedure that I. P. Pavlov set in order to observe the alternations of dog's saliva and digestive fluid secretion in response to feeding, he observed that the subject's (i.e., dog's) saliva and digestive fluid were also secreted every time he and his associate arrived at the laboratory. Consequently, I. P. Pavlov decided to experimentally examine the functional mechanisms and structures that let the dogs to also secrete saliva and digestive fluid in his presence rather than exclusively to the presence of food in response to which the dogs reflexively secrete saliva and digestive fluid (Spence 1978).

Ultimately, I. P. Pavlov came to the conclusion that the food was associated with the occurrence of his associate by the subjects (i.e., dogs) as the two stimuli had been repeatedly paired. Specifically, the sound of the bell which at the beginning was a neutral stimulus, that is, a stimulus that did not elicit a particular response, acquired the capacity to elicit a response that was qualitatively similar to the one that the food naturally and automatically elicited. The response of the dogs became classically conditioned and respectively

the sound of the bell turned into a conditioned stimulus. Consequently, the new response that was learned as a reaction to the sound of the bell is named conditioned response (Spence 1978).

The Discrepancy Between Unconditioned and Conditioned Responses

Ivan Petrovich Pavlov had proposed through his work on conditioned reflexes that the same response that was elicited by an unconditioned stimulus could also be elicited by a conditioned stimulus through its association with an unconditioned stimulus (McSweeney and Murphy 2014). However, it quickly became clear that conditioned responses are of lower intensity than unconditioned responses. In addition, research related to classical conditioning after I. P. Pavlov's work has reliably proposed that the unconditioned response and the conditioned response are not the same responses, but they are usually qualitatively similar. Yet, this could be significantly different. Specifically, it has been cited that I. P. Pavlov's dogs did not confuse the sound of the bell with nutriment, but they responded to the association among the sound of the bell and nutriment that consistently presented right after the first (Ramnero and Torneke 2011). In addition, the unconditioned response as well as the conditioned response are not limited to the secretion of saliva. Specifically, the secretion of saliva constitutes just a part of a multifaceted response through which the body of the dog is being prepared for obtaining nutriment (Staddon 2014).

Emotional Reactions Based on Unconditioned Responses

Research related to classical conditioning has consistently suggested that affective responses are governed by unconditioned responses, which have been shaped through evolutionary history to help humans to adapt and survive (Baum 2017). Research related to the affective reactions

that are based on unconditioned responses has consistently suggested that humans possess a physiological system that responds to specific unconditioned stimulus. However, the scientific knowledge related to the environmental conditions (unconditioned stimuli) that induce affective reactions is limited. Specifically, the research related to the mechanism and/or conditions that induce such affective responses has not been yet fruitful. This is because, the majority of research studies have included adults as participants, yet, an adult person plausibly has a long-term history of learning (McSweeney and Murphy 2014). However, it has been consistently cited that there are numerous stimuli that are not learned (unconditioned stimuli) yet induce some affective responses. For instance, the affective response of fear can be naturally induced by unconditioned stimulus such as clamorous sound, objects getting near fast, loud noises, and specific facial expressions of other individuals (Thines 1987). Through the lens of an evolutionary perspective, it is not plausible to presume that there is just one kind of stimulus that is able to induce, for instance, fear or anger. That is, if these emotional responses ought to enhance adaption, and thus help an organism to survive, they must be triggered in numerous settings, yet the discrepancy between the stimulus would not have to be very high to have an influence early in a person's life (Baum 2017).

Unconditioned Stimulus

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

[Biologically significant stimulus](#); [Unconditional stimulus](#); [Unconditioned reflex](#)

Definition

Unconditioned stimulus is any stimulus that has the capacity to reflexively induce a biological reaction which usually enhances adaption and survival.

Introduction

Living organisms are endowed with a number of responses to unconditional stimuli to prepare them to adapt and survive (Baum 2017). Unconditional stimuli refer to any stimuli which naturally and automatically induce innate reactions, that is, reactions that are not learned by living beings; they are biologically endowed to them to be able to respond to unconditioned stimuli (McSweeney and Murphy 2014). The reactions that are induced by unconditioned stimuli are referred to as unconditioned responses since they arise automatically and naturally. For instance, an individual who receives a puff of air in the eye area responds with an eyeblink. The puff of air

constitutes an unconditioned stimulus and respectively the eyeblink an unconditioned response. When a puff of air moves toward the eye area, people blink (Shanks 1995). They do not need to learn this response as they are biologically prepared to do it (Thines 1987). The eyeblink biologically operates to safeguard the eye.

Classical Conditioning and Unconditioned Stimuli

In the most well-known experimental study of Ivan Petrovich Pavlov that was conducted with dogs, the aroma of food was the unconditioned stimulus. Specifically, in this experimental study the dogs were smelling the aroma of the food and in response they automatically as well as naturally began to secrete saliva and digestive fluid. The natural, that is, the unlearned, contingency of a stimulus that evokes a response in that trial was the relationship among food and salivation which represents the contingency of an unconditioned stimulus and an unconditioned response. The term stimulus denotes an event that precedes the response that is investigated (Spence 1978).

Emotional Reactions Based on Unconditioned Responses

Research related to classical conditioning has consistently suggested that affective responses are governed by unconditioned responses, which have been shaped through evolutionary history so that to help humans to adapt and survive (Baum 2017). Research related to the affective reactions that are based on unconditioned responses has consistently suggested that humans possess a physiological system that responds to specific unconditioned stimulus. However, the scientific knowledge related to the environmental conditions (unconditioned stimuli) that induce affective reactions is limited (Schachtman 2011). Specifically, the research related to the mechanism and/or conditions that induce such affective responses has not been yet fruitful. This is because, the majority of research studies have included adults as

participants, yet, an adult person plausibly has a long-term history of learning (McSweeney and Murphy 2014). However, it has been consistently cited that there are numerous stimuli that are not learned (unconditioned stimuli) yet induce some affective responses. For instance, the affective response of fear can be naturally induced by unconditioned stimulus such as clamorous sound, objects getting near fast, loud noises, and specific facial expressions of other individuals (Ramnero and Torneke 2011). Through the lens of an evolutionary perspective, it is not plausible to presume that there is just one kind of stimulus that is able to induce, for instance, fear or anger. That is, if these emotional responses ought to enhance adaption, and thus help an organism to survive, they must be triggered in numerous settings, yet the discrepancy between the stimulus would not have to be very high to have an influence early in a person's life (Baum 2017).

Definition

Mental processes, including inferences, judgments, motivations, and internal conflicts, of which the individual is not consciously aware.

Introduction

The concept of the unconscious mind first became widely known in Freud's work, where it plays a central role in all human activity as an unseen cause or motivation. Although much of Freud's theory has long since dropped out of favor in the scientific psychological community, the central notion that we are often not consciously aware of our own motivations, and that those motivations are often sexual, or perhaps repressed memories of long-forgotten trauma, continues to broadly impact popular culture into the twenty-first century.

Unconscious Conflict

As the *id*, the most primitive part of the human personality, comprising our basic instincts and biological drives for food and drink as well as the sex drive, cannot delay gratification, those fundamental drives inevitably come into conflict with societal rules and laws, internalized as the *superego*. The *ego*'s ability to resolve those conflicts is not perfect, thus leading to feelings of anxiety and guilt which motivate much of what we do. As the *id* and *superego* are both part of the unconscious mind, this conflict, according to Freud, is also entirely unconscious.

A foundational notion of psychoanalytic theory, therefore, is that much of what drives human activity is not directly accessible to the conscious mind and must be discovered indirectly. His favorite means of accessing his patients' unconscious motivations was via dream analysis.

Dreams: The Royal Road to the Unconscious

Freud argued that the primary function of all dreams is wish fulfillment, including fulfillment of the secret desires which we cannot admit even to ourselves on a conscious level.

Understanding our dreams, therefore, requires recognizing that they have become distorted in order to conceal the underlying wishes. The surface content, or *manifest content*, is a heavily disguised version of unconscious wishes and desires, which he called the *latent content*. Understanding the contents of the subject's unconscious mind therefore requires correct interpretation of the symbolic meaning of that individual's dreams.

According to Freud, many of our unconscious motivations are so unacceptable to us that they create a great deal of intrapsychic conflict between the ego and the unconscious parts of the mind. The only way to alleviate the tension and anxiety resulting from that conflict is to allow the forbidden content to surface, though heavily disguised, in dreams. The disguise is necessary because even in dreams, the individual's resistance to these unacceptable impulses remains too strong to acknowledge them directly. The dream's real significance is completely concealed from the dreamer, and dreamers are unable to grasp the actual meaning of their dreams without the help and guidance of the psychoanalyst.

Unconscious Sexual Motivation

Freud was of course notorious for his emphasis on sexuality in his descriptions of the conflicts that roil the unconscious mind. His dream analyses often emphasize the hidden sexual content of dreams, which is unsurprising given the central place occupied by sexuality in his explanation of

mental illness. He famously described the Oedipus complex, an unconscious struggle over a child's desire for the opposite-sex parent, as the "nuclear complex" of all neurosis, arguing that adult mental life simply cannot be understood without analysis of this unconscious conflict from early childhood.

The Parapraxes (or Freudian Slips)

Parapraxis is a Greek term that translators of Freud (although, interestingly, the term does not appear in the original German text, so it was never actually used by Freud—the term he actually used, *Fehlleistungen*, may have been considered too challenging for the Anglophone audience) used to refer to the notion that errors in speaking can reveal the speaker's hidden, unconscious concerns, wishes, or conflicts, just as surely as they can be discerned in dreams. In popular culture, the concept has become so associated with Freud that the common term for such an error is a *Freudian slip*. A widely reported example of such a slip, which caused much mirth among political reporters on American television, occurred when Condoleezza Rice, in her role as National Security Advisor to President George W. Bush, referred in a press conference to a conversation with her boss, beginning, "As I was telling my husb—," stopping herself before completing the thought. This was widely reported in a way heavily influenced by Freud, as a sign of buried sexual tension in their professional relationship, and is easily found via a Google search for *Condoleezza Rice Freudian slip*.

The Cognitive Unconscious

Although Freud's version of the unconscious mind has largely disappeared from scientific psychology, the notion that many of our mental processes occur without conscious awareness is central to modern cognitive and social psychology. Slips of the tongue (no longer called Freudian slips) are actually still studied, as they can reveal useful information regarding how word meanings and word sounds are stored in the brain.

According to recent cognitive research, more than 80% of slips share an initial sound with the intended word, and more than 70% of word endings are identical or very similar as well. While not as immediately intriguing as the notion that a slip indicates hidden sexual desire, this information has led to the modern understanding of the extent to which words are stored in memory in an *echoic* store (by sound) rather than an *iconic* (visual; stored according to similarities in how the words *look*) store. This in turn provides an explanation of the tip-of-the-tongue phenomenon, in which it is often possible to remember the initial or final sounds in a word while being nonetheless unable to recall the word completely. This happens because, since words are stored by sound, sometimes the attempt to retrieve a word activates traces of similar-sounding words, but not the desired word, leading to either a tip-of-the-tongue error (failure to retrieve the word) or the production of a wrong word which was triggered by the search for the correct one (a slip of the tongue, but not Freudian in nature). From both perspectives, complex unconscious processes are involved, but the unconscious processes proposed by more scientifically minded psychologists are quite different from those suggested by Freud.

Understanding Human Gaze

Rosemary Bettle and Alexandra G. Rosati
Department of Human Evolutionary Biology,
Harvard University, Cambridge, MA, USA

Introduction

The ability to detect the focus of an individual's visual attention can provide rich information about the location of important objects in the

larger environment, as well as about that individual's internal psychological states. Detecting and using such information about gaze direction is a foundational component of human social behavior. For example, even young infants are sensitive to the direction of other's gaze (Flom et al. 2007) and begin to follow gaze geometrically to objects beyond their immediate view in the second year of life. Humans also utilize eye contact as a cue of joint attention – that two individuals are together looking at the same thing. This skill thus allows humans to engage in a variety of potentially species-unique social behaviors, including communication about cultural knowledge (Csibra and Gergely 2009). Finally, our ability to attend to the same stimuli as other individuals is vital to normal social development, providing a scaffold for the development of other abilities such as theory of mind and language acquisition.

Yet despite these links to many complex abilities in humans, sensitivity to gaze is not unique to our species (Rosati and Hare 2009). In fact, gaze-following is widespread across the primate order, as well as in other social mammals and even in some reptiles. Yet these gaze-sensitive behaviors are not necessarily underpinned by the same cognitive processes across species. Comparative cognition researchers are therefore faced with two related questions. First, what are the psychological bases for this skill, and how do they differ across taxa? Second, why does gaze-following appear to contribute to the emergence of complex social cognitive traits in some taxa, such as humans, but not necessarily in others? By answering these questions, we can begin to understand the evolutionary origins of human-unique social cognition.

Psychological Basis of Gaze-Following Across Primate Species

Gaze-following is phylogenetically widespread in primates (Rosati and Hare 2009; Shepherd 2010). Representatives of all major primate groups follow the gaze of others in some situations, including great apes, many Old World monkey species, New World monkey species, and even some lemur species.

However, several aspects of gaze-following behavior differ across taxa. A key distinction is the degree to which gaze-following behavior relies upon more reflexive mechanisms that drive individuals to co-orient – looking in the same direction as others without really understanding why – versus whether gaze-following stems from the attribution of a mental state to another individual. In the first situation, individuals may learn through trial-and-error experience that they gain useful information when they look in the same direction as others, whereas in the latter individuals actually understand that others are looking somewhere because there is something interesting in that direction to see.

As in humans, gaze-following in apes appears to sometimes involve mental state attribution (Call and Tomasello 2008). One piece of evidence comes from experiments using geometric gaze-following (Okamoto-Barth et al. 2007). Within these paradigms, the object that the actor looks at is not within the subject's immediate line of sight, so the subject must move and reorient their position in order to observe the focus of the actor's gaze. Thus, geometrical gaze-following requires the ability to generalize between their own egocentric perspective and that of the actor. The fact that chimpanzees, bonobos, gorillas, and orangutans (see, e.g., Okamoto-Barth et al. 2007) will move in order to view what the observer is looking at makes it unlikely that the behavior is the result of a simple rule to turn their head when other individuals do. Rather this appears to be a more flexible response where the apes are trying to ascertain what the other can see. Moreover, chimpanzees in particular robustly use information about both humans' and conspecifics' current or past visual perspective in competitive contexts (Call and Tomasello 2008). This provides strong evidence that at least some apes can use information about where others are looking to infer their subjective perceptions and knowledge. Along the same lines, rhesus monkeys seem to use information about other's visual perspective during competitive interactions, as well as to predict how others will act (Martin and Santos 2016).

However, there is increasing evidence that gaze-following may be more reflexive and egocentric in other primate species. First, several

monkey species are unable to incorporate gaze information to predict the behavior of humans or conspecifics based on where they were looking previously. Second, unlike chimpanzees or rhesus macaques, several other species do not seem to use information about what others can see in competitive contexts, including capuchins and common marmosets. Finally, while some lemurs have been shown to co-orient with conspecifics during their natural interactions, they may fail to follow the gaze of a human demonstrator in more controlled contexts. However, this may vary across even closely related species: whereas ring-tailed lemurs show a basic gaze-following response to human gazing and also use information about where a human competitor is looking when deciding whether to approach a contested piece of food, several other species of lemur do not (Sandel et al. 2011). Taken together, this suggests that some instances of gaze-following behavior in monkey and strepsirrhine primate species – which can appear behaviorally similar to great ape gaze-following in many respects – might in fact be due to quite different cognitive processes.

A final piece of evidence that the cognitive basis of gaze-following may differ across species comes from studies that compare the ontogeny of these behaviors. In humans, reliable gaze-following emerges within the first year of life. Across nonhuman primates, however, there is quite some variability. In nonhuman apes, gaze-following emerges around 3 to 4 years. In pig-tailed macaques, gaze-following may not emerge until adulthood – leading to the hypothesis that nonhumans require a much longer period of social experience to acquire this behavior. Yet closely related rhesus macaques exhibit gaze-following behavior during infancy, more like humans (Rosati et al. 2016). Overall, this suggests that gaze-following in different species may depend on different social experiences or underlying cognitive mechanisms. Further comparative work examining the ontogeny of social cognition can help elucidate why some species develop social cognitive skills at a different pace and why species may develop certain social cognitive skills but not others.

The Adaptive Value of Gaze-Following

Gaze-following and other gaze-sensitive behaviors appear to be biologically important, given that this skill has evolved in many taxa. In general, this social response may allow diverse species to engage in several important behaviors such as avoiding predators and locating food items in the environment. Yet the cognitive basis of gaze-following differs between species: in humans and other great apes, the ability to model another individual's mental states seems to drive gaze-following, whereas in other species gaze-following may be more egocentric. There are two main evolutionary hypotheses accounting for this variation, and in particular why mind-reading abilities might emerge in some species but not others.

One influential idea is that social competition drives the evolution of theory of mind abilities. If animals can think about other's visual perspective in competitive contexts, this enables more sophisticated deception and counter-deception. This hypothesis is supported by the fact that many primates seem to show their most sophisticated abilities to think about the direction of other's gaze in competitive situations. In contrast, many nonhuman species have difficulty using gaze cues in more cooperative situations, such as "object choice" paradigms in which a human helpfully looks at the location of a hidden food item to communicate this information. In fact, many diverse primate species fail to use such cues.

Yet gaze-following may hold a different adaptive role in humans (Tomasello and Carpenter 2007). Our species may follow gaze to enable successful *cooperative* behaviors. Humans are especially reliant on eyes in gaze-following situations, and eyes subsequently evolved a new social function in human evolution, to support cooperative (mutualistic) social interactions. The "cooperative eye hypothesis" posits that our species' unique eye morphology is an adaptation allowing individuals to view each other's gaze direction with greater precision, enabling these cooperative behaviors. These morphological changes include a white sclera with high contrast to the iris, along with an enlargement of the visible part of the sclera,

and they may explain why humans are especially sensitive to eye direction (compared to face direction or whole-body cues) relative to other species. These changes may allow humans to engage in large-scale cooperative behaviors between non-kin, which appear to be human unique.

More generally, humans appear to be uniquely motivated to participate in "joint attentional interactions," collaborative interactions where the actors usually monitor each other's visual attention in order to better coordinate. Building on this proposal, Csibra and Gergely (2009) have argued that eye contact is a type of cue that humans use to mark the transfer of pedagogical information. In response to such pedagogical cues, infants infer that the information that follows will be culturally relevant information about their social world (Csibra and Gergely 2009). This theory predicts that other species lacking human-like culture and teaching will not respond to such ostensive cues in the way that humans do. However, it remains untested whether other primates do in fact exhibit any similarities with humans in their responses to such cues.

Conclusions

Why are so many species sensitive to gaze direction? Gaze direction information may be useful because other individuals tend to gaze at biologically relevant stimuli, because this information allows an individual to make inferences about another individual's mental state, because gaze is used as an explicitly communicative signal, or because information about gaze direction helps to scaffold the development of other cognitive skills. It is likely that the adaptive purpose of gaze sensitivity varies between taxa, despite the superficial similarity of gaze-following behaviors in many species. Therefore, comparative analysis of the cognitive basis of these skills can illuminate the selective pressures that have resulted in divergent social cognitive skills across taxa. This is of particular importance in light of the hypothesis that the evolutionary origins of human-unique social cognition can be understood as the result of a selective pressure resulting from cooperative

interactions or unique patterns of sociocultural learning. If so, human gaze sensitivity might be uniquely adapted to support such behaviors, for instance, via involvement in processes such as joint attentional interactions or pedagogical learning. Gaze sensitivity therefore provides a window into the selective pressures that have characterized social cognitive evolution between taxa, which may enable researchers to begin to uncover the roots of human-unique cognition.

Definition

The comprehension of human gestures, specifically points, as referential and communicative symbols.

Introduction

The main question to be addressed in this chapter is are nonhuman animals capable of understanding human-given points as communicative symbols? Are they capable of understanding the referential intention of the act of pointing? To truly answer these questions, it is first necessary to discuss how *humans* grow to understand the referential and communicative nature of points. Many argue that this capacity is not innate but develops gradually as the child gains experience with both seeing and performing the action as well as with the advances in theory of mind that occur with age (Woodward and Guajardo 2002). To be able to successfully follow a point given by another individual, the point-receiver must first understand that the point is communicative – conveys information – as well as then understand that the action of the pointer was performed intentionally, with purpose and direction. The information conveyed in the point must then be extracted by inference (Moore 2016); it could be simply directing attention to a specific aspect of the environment, it could be part of a more complex set of cues directing the receiver to perform a sequence of actions with the referent of the point, and so

on. The communicative *context* in which the point was given must be considered by the receiver in order to extract the information accurately. This task becomes more complicated if the point referent is ambiguous or the point is poor quality (e.g., in the general direction of the referent, but fleeting and nonspecific). Per Woodward and Guajardo's (2002) work, the idea that a point is object directed, emerges between 9 and 12 months of age. This work was supported by Pfandler et al. (2013) who demonstrated that the comprehension of points by human infants showed a developmental trajectory between birth and 18 months, suggesting that experience with the pointing action and advances in theory of mind are important to the understanding of points.

Pointing in Nonhuman Animals

The task, then, becomes increasingly difficult for nonhuman animals. Broadly speaking, one task has been used predominately to test animals' abilities to follow human points in most comparative research: the object-choice task. The task is simple to perform by experimenters and yields easy to quantify responses from the animals, in most cases. The basic experimental design places the experimenter equidistance between (or behind) two occluders (e.g., opaque cups or buckets). The experimenter then places a desired item (e.g., food or a toy) under one occluder, being careful to also falsely bait the other occluder either before or after truly baiting so that the animal cannot use any alternate strategy to locate the hidden object. The experimenter then points (or gestures in some manner) to the location of the hidden object and waits for the animal to indicate their choice of location – either the correct occluder where the object is hidden or the incorrect occluder where the object is not located. A choice for the animal can be indicated by touching the occluder with their hand/finger, nose, or paw, by direction of gaze, or coming within a certain distance of the occluder. If the animal chooses the correct location, the experimenter then rewards the choice by giving the object to the animal. Many variations of type of point or

combination of visual cues (e.g., gazing in the direction of the correct occluder while pointing) can be utilized. This method is also used in work with human infants.

In human infants, gains in theory of mind are vital to understanding points. Research on theory of mind in nonhuman animals, however, has led to contradictory conclusions. Some researchers would argue that even in our closest evolutionary relatives, primates, evidence is limited, if present at all, rendering the possibility of them understanding human points improbable. Tomasello et al. (1997) and Povinelli et al. (1997) independently concluded that apes were unsuccessful at completing the object choice task, thus incapable of understanding human points. They argue that apes lack the ability to understand the intentionality behind the communicative gesture, despite demonstrating a use of basic gestures in the wild to communicate with group members. Why might they be able to follow gestures given by conspecifics but fail at demonstrating the skill with human pointers? It could be argued that nonhuman primates do not see humans as communicative partners; therefore, they cannot extract the communicative intent from the gesture; the communicative goal is lost in interspecies translation.

If our closest living relatives are incapable of following human-given points by this argument, then what species could be capable? The answer, according to Hare et al. (2002), is domesticated dogs. If apes do not see humans as communicative partners, it could be because of lack of the need for interspecies cooperation. Domesticated dogs, however, have been bred for over 10,000 years to work cooperatively with humans and, therefore, may possess the abilities not shown in apes by necessity. Hare et al. (2002) proposed an explanation for why domesticated dogs appear to show a heightened ability to understand human points over apes in the *domestication hypothesis*, stating, "selection pressure on dogs during the process of domestication [resulted in] specific skills of social cognition and communication with humans" (p. 1635).

Support for an evolutionary predisposition for understanding human communicative gestures has been shown in work looking at the ontogeny

of point following, finding that even very young puppies (less than 1 month of age) could follow human points. These results suggest that experience with humans as communicative partners is not necessary for puppies to understand the communicative and referential nature of points; instead, this ability is a result of selective pressures during domestication (Gasci et al. 2009; Hare et al. 2002). Further support for the domestication hypothesis can be found when comparing the performance of domesticated dogs to that of wolves. As all living domesticated dog breeds were bred from wolves, genetically, these two groups are very similar, but both have experienced different selective pressures in their evolutionary histories. If wolves demonstrate similar capacities to domesticated dogs, it would undermine the premises of the domestication hypothesis. However, the results of tests comparing wolves and dogs on point following tasks found that wolves were not successful on the object-choice task, regardless of their exposure to humans as many of these studies were conducted with captive wolves in sanctuaries and rehabilitation facilities (Gasci et al. 2009; Hare et al. 2002). Even wolf puppies raised with humans took significantly longer than domestic puppies to learn to follow human points (Gasci et al. 2009), supporting the premises of the domestication hypothesis and further explaining why apes notoriously are unsuccessful at using human communicative cues. Importantly, though, Gasci and colleagues' (2009) discovery that while it took longer for wolf pups to learn to follow human points, that skill could be *taught*, suggesting that perhaps evolutionary history is not the entire story when it comes to social cognition, a topic to be discussed further in the next section of this chapter.

As it is in all of science, there was not universal acceptance of the premises of and evidence for the domestication hypothesis. Two areas of contention focused on (1) the assertion that selective pressures in the evolutionary history of a species are more important than the environment in which they developed (ontological pressures) and (2) discrepancies between the object-choice methodologies being used to compare performance between species. Starting with the first concern, very little

in nature is the result of one type of selective pressure. Domestication, granted, is a multi-dimensional pressure, but after thousands of years of other selective pressures and, importantly, differential ontological contexts, assuming the cognitive toolkits remain entirely conserved seems highly unlikely. Notably, not all dog breeds were designed for cooperatively working with humans; some breeds were simply bred for companionship and aesthetics, suggesting that the ability of all dog breeds to follow points in a cooperative setting would not be necessary and, therefore, may not be conserved. Udell et al. (2008) tested point following using an object-choice task with domesticated dogs housed in animal shelters, varying tremendously in their exposure to humans as social partners, to human-reared wolves, who had been raised since puppies with humans. They found that highly socialized wolves outperformed under-socialized dogs consistently, supporting that ontological forces can make as much of an impact on the social cognitive skills of animals as can their evolutionary histories. In further support, the importance of rearing environments and exposure to humans as communicative partners comes from work with apes (bonobos and chimpanzees), finding that those animals raised in highly enculturated environments (long-term exposure to humans as communicative partners) *could* follow human given points, whereas those raised with less exposure to humans in traditional housing facilities struggled to comprehend points (Lyn et al. 2010). These results indicate that experience with humans as communicative partners during development shapes their abilities to follow human points; therefore, the skill is learned not necessarily entirely evolutionarily based.

The second concern with the studies supporting the domestication hypothesis centers around methodologies. While the object-choice task is similar in nature, minor adjustments to the experimental set up can make a major difference for the animals' abilities to follow the points. Udell et al. (2013) discuss that the distance between the two occluders (proximal [close together] or distal [far apart]) and the type of point used (dynamic [moving] or static, proximal

[close to the occluder] or distal [far away from the occluder], momentary [fleeting] or constant) can all make a major difference in the way the point is interpreted by the animal. Previous failures to succeed at the task may not be the result of an inability to follow points, but confusion based on the task design itself. For instance, dogs were not equally successful at all varying point types, suggesting that experimental set up is important and experience with pointing allows for the dogs to continually learn and adapt to the cues, improving their performance after exposure (Udell et al. 2013). Importantly for comparison purposes, much of the research conducted with apes (e.g., Povinelli et al. 1997) used a single type of point – static, proximal occluder position (within 3 ft [0.9 m], distal point position (1 ft [0.3 m] or more from the occluder). This point type places the experimenter *behind* the point referent; therefore, the point is displaced from the object, making it difficult for the animal to trace the sight line from the point to the referent. In addition, due to safety concerns, there is always a barrier between the ape and the experimenter, which also could obstruct the apes' ability to trace line of sight or physically align themselves from the frame of reference of the pointer. Using varied point types with dogs and testing them without barriers between the pointer and the animal could lead to improved performance without any evolutionary history effects. Truly comparative work, using the exact same methodologies between species, is necessary to rule out these possibilities.

Conclusion

Research looking at the abilities of nonhuman animal species to understand the communicative and referential nature of human points is ongoing, looking at many other species, both domesticated and nondomesticated, to elucidate the evolutionary history of the ability. It is an important skill to study as it provides knowledge of the perspective taking, social cognition, and theory of mind abilities of other species. In addition, it allows for the study of how exposure to humans in captive environments has shaped the cognitive toolkits present

in a wide variety of species. Discovering the phylogenetic roots of this ability also provides great insight into the evolution of human language, particularly ostensive communication (Moore 2016).

Definition

Some evolutionary theorists link suicide terrorism to low-status males, which in many societies translates into lack of employment or underemployment.

Introduction

One theory of suicide terrorism proposes that attackers will tend to be young males with poor mating prospects. Contending that the sanctioning of polygyny in Islam excludes young, low-status males in some Muslim societies from the mating market, Kanazawa (2007) concludes that suicide terrorism is a byproduct of intrasexual competition. Male reproductive success is constrained by access to mates, and males with higher social status are more likely to be polygynous and/or have greater reproductive success (Chagnon 1988; Turke and Betzig 1985). In modern industrial or postindustrial societies, a positive employment status and high income is associated with greater access to mates and higher reproductive success in males (Hopcroft 2006). Mating competition among males increases risk-taking and aggressive behavior (Wilson and Daly 1985); thus, Kanazawa argues that suicide terrorism relies on the activation of mechanisms associated with intrasexual competition and sexual access manipulations. This theory is not supported by empirical evidence (see ► [Sexual Access Manipulation](#); ► [Young](#)). There is no evidence that unemployment is associated with suicide terrorism at the individual level.

Low Social Status Not Associated with Suicide Terrorism

The data contradict the claim that suicide terrorists have significantly lower status than other males in the populations from which they come in terms of income, education, and employment (Atran 2003; Berrebi 2003). According to Berrebi (2003), suicide attackers in the West Bank and Gaza Strip

came from wealthier families and were more likely to have a high school education compared to the general Palestinian population. Krueger and Maleckova (2003) found similar results among Hezbollah suicide terrorists, concluding that poverty and low educational attainment are not risk factors suicide terrorism at the level of the individual. On the other hand, Atran (2003) suggests that a relative loss of employment and economic opportunities among the educated might be a precipitating factor in suicide terrorism, reporting that a rise in unemployment and wage decreases among college graduates corresponded with the rise of the First Palestinian Intifada. Other studies such as Saleh (2004) have found a correlation between unemployment rates in the occupied territories of Palestine and terrorist attacks in those regions.

Conclusion

Studies indicate that suicide attackers are not low-status males, and though they are typically unmarried, there is no evidence that they would have remained unmarried if they lived to mate and reproduce. Suicide attackers tend to have middle class backgrounds and high education levels. However, terrorism is associated with regional poverty. In sum, suicide terrorists typically come from poor regions but tend to be better off in terms of wealth and education compared to others in their local communities.

Definition

Counter to what is seen in most countries, women are intimate partner violence perpetrators at a similar rate as are men in the United States. Aggression is modulated by environmentally sensitive brain mechanisms. The United States provides a unique set of societal forces that through these mechanisms promote higher levels of female-initiated intimate partner violence relative to other nations.

Introduction

Traditionally, men have been stereotyped as being perpetrators of intimate partner violence (IPV), whereas women have been depicted as victims. Early research suggested that if women were aggressive toward their male partners, it was in the context of self-defense (e.g., Dobash and Dobash 2004). However, in the last 50 years, research from the United States has suggested that women are just as likely to be the perpetrators of IPV, and in many samples they have been shown to be more aggressive than men (Archer 2000, 2006). In a meta-analysis, Archer (2000) found that women in the United States were slightly more likely to engage in physically aggressive acts than men and to use such acts more frequently. Further, women have been reported to engage in male-directed IPV even when in relationships with nonviolent men (Stets and Straus 1992). Some researchers (e.g., Archer 2006) have suggested that the higher rates of female-to-male-perpetrated aggression are unique to the United States and other Western cultures, a finding that needs explanation. This entry provides an examination of what factors might account for the unusually high use of aggression by women in the United States in the context of IPV.

Sociocultural Factors and IPV Symmetry

Several social factors have been identified as being associated with higher levels of aggression in women in the context of IPV. First, gender equity and empowerment are correlated with patterns of IPV (Archer 2006). Women in both low and highly empowered nations are known to use violence against their male partners, but levels of male-to-female-directed IPV are lower than in countries with lower levels of gender empowerment. Therefore, in the highly gender-empowered United States, women's IPV perpetration levels are higher and men's are lower, resulting in a pattern of gender symmetry. Further, the United States is an individualistic culture, and women are

more likely to be aggressors of IPV in cultures characterized higher on this trait relative to collectivism (Archer 2006). Another factor that seems to promote symmetry in IPV perpetration is economic independence. Archer (2000) reports that lower dependence on men for financial support is associated with lower victimization of women and higher levels of IPV perpetration by women. Many women in the United States work outside of the home, which provides them with economic independence. This economic independence has shifted the social structure in the United States. Women are not only less dependent upon their male partners for support, but they also are less likely to be subjected to the coercive power of their husband's kin. In combination with the Western attitudes prohibiting the use of male-to-female aggression and the resulting decreased fear of retribution for hitting men (e.g., Fiebert and Gonzalez 1997), women in the United States lack some of the constraints preventing women in other countries from engaging in the risky use of physical violence against men.

Weapon availability. In general, men are more likely than women to commit homicide (Daly and Wilson 1988). Further, men commit uxoricide at a much higher rate in the United States relative to other countries, including other Western countries (Wilson and Daly 1998). However, as is true of nonlethal IPV, the sex ratio for spousal killing in the United States is more equal than elsewhere in the world (Wilson and Daly 1992). When women kill their male partners in the United States, they are more likely to use guns than any other weapon (Mize et al. 2009). Men are inherently larger and stronger than women, but the availability of guns in the United States serves to equalize those differences making it easier for women to kill their male partners.

Conclusions

In the United States, men and women are almost equally likely to be the perpetrators of IPV. Trivers (1972) parental investment and sexual selection theories would predict that men would be more likely to use risky competition strategies, including

physical aggression. However, the mechanisms underlying aggression are sensitive to environment and social cues (Goetz 2010). The conglomerate of societal factors that prevail in the United States changes the cost-benefit analysis of aggression for women, altering the social strategies that they use to settle interpersonal conflicts in the context of intimate partner relationships (Cross and Campbell 2013). This is manifested in a more symmetrical pattern of IPV perpetration between men and women in the United States relative to what is seen between the sexes in many other countries.

Universal Aspects of Kinship

[Kinship universals](#); [Panhuman manifestations of genealogical relationships](#)

Definition

Behavioral aspects of kinship found in all human societies.

Introduction

Humans exhibit by far the most extensive and internally differentiated networks of kinship of all animal species. Correlatively the importance of kinship in regulating social life in humans is unequaled in the animal world. If this is not evident in modern state societies in which kin represent a small fraction of an individual's social network, it is salient in small-scale societies, notably in groups of hunter-gatherers whose mode of subsistence characterized our ancestors over 99.5 % of the 2.5 million years of evolution of the genus *Homo*. If only for that reason, kinship is expected to have played a central role in shaping the social life and social cognition of hominins and hence to be deeply ingrained in human nature.

Unsurprisingly from that perspective, cultural anthropology was born with the scientific study of kinship when Lewis Henry Morgan published his *Systems of Consanguinity and Affinity of the Human Family* in 1871. One hundred years later, Robin Fox could still state that “kinship is to anthropology what logic is to philosophy or the nude is to art; it is the basic discipline of the subject” (Fox 1967, p. 10). Why is that? Why is kinship so important in human affairs? The most basic reason is perhaps that kinship is not a domain of social activities like politics, religion, or economics but an *intrinsic* characteristic of relations between individuals determined by how they are connected to each other through parent-child links. That characteristic has some fundamental properties (discussed below), which result in kinship structuring social life at all levels of analysis – social acts, social interactions, enduring social relationships, group structure, and between-group relations – and in virtually all domains, from domestic activities to politics to religious practices.

Given that all aspects of human kinship are extremely variable across cultures, the present focus on the universal aspects of kinship may not be immediately obvious. Diversity is so pronounced that most anthropologists have concentrated on studying cultural particulars and emphasized cultural differences in kinship systems and kin terminologies rather than

similarities. Cultural variation, however, results from universal principles operating in different socioecological contexts, from which it follows that any theory purporting to explain cross-cultural similarities and differences must necessarily integrate information about the universal constraints regulating the observed variation. Accordingly, three broad categories of kinship universals are defined here, which pertain, respectively, to the intrinsic properties of kinship (*intrinsic universals*), the universal characteristics of kin recognition (*kin recognition universals*), and the universal characteristics of certain types of kinship bonds (*relational universals*). Because a substantial fraction of those universals stem from our common evolutionary heritage with other primates, the present review proceeds by distinguishing the features we share with non-human primates from those that are specific to our species.

Intrinsic Kinship Universals

Much of the impact of kinship on social life lies in three of its intrinsic properties: kinship affects an individual’s social motivations, it is a permanent characteristic of dyadic relations, and it engenders genealogical structures. Those properties account for some of the most fundamental kinship universals (Table 1).

As in now overwhelmingly documented throughout the animal kingdom, kinship promotes prosocial behavior between relatives. Kin selection (or inclusive fitness) theory is the primary mechanisms involved. Briefly, when a female

protects her daughter, granddaughter, or sister against an aggressor or a predator, she does not gain any direct (personal) benefits, whether immediate or delayed. On the contrary she incurs costs, but by reducing the likelihood that her kin will be wounded or killed, she obtains indirect fitness benefits amounting to a fraction of the direct benefits accruing to her kin, that fraction being determined by their degree of genetic relatedness – in other words, she increases her inclusive fitness. Kin selection theory thus accounts for the existence of both unilateral and bilateral altruism between relatives.

Kin selection is also expected to favor cooperation between kin, whether mutualistic cooperation (activities in the course of which the participants obtain immediate personal benefits) or reciprocity (the participants obtaining personal benefits, but in alternance). This is because when a female cooperates with a kin, she benefits in two different ways. She obtains the direct (personal) benefits of the cooperative act – as she does when interacting with a nonkin – and she derives the indirect fitness benefits previously mentioned. Thus, other things being equal, such as the competence levels of potential partners (Chapais 2006), cooperation between kin pays more than cooperation between nonkin (Wrangham 1982).

In addition to promoting prosocial behavior, kinship has inhibitory effects on sexual behavior: it decreases levels of sexual attraction between close kin. The avoidance of incest is the rule in humans and other primates (Paul and Kuester 2004; Wolf and Durham 2004; Chapais 2008). Incest avoidance is adaptative owing to the biological costs of inbreeding – the reduction of an

Universal Aspects of Kinship, Table 1 Three intrinsic properties of kinship and the corresponding *intrinsic kinship universals*

Intrinsic properties of kinship	Intrinsic kinship universals
Determines social motives	Kin biases in unilateral/bilateral altruism
	Kin biases in mutualistic cooperation
	Kin biases in reciprocity (social exchange)
	Kin biases in social allegiance
	Incest avoidance
Permanent characteristic of relationship	Enduring bonds between biological kin
	Enduring bonds between affines (in-laws)
Engenders genealogical structures	Kinship structures (e.g., lineages, clans)
	Multigroup kinship networks (alliances)

organism's reproductive success due to a lowering of its fecundity or its offspring's chances of survival (for a review on the costs of inbreeding in nonhuman primates, see Charpentier et al. 2007). The avoidance of incest appears to be mediated through the correlates of close kinship bonds such as developmental familiarity, intimacy, and attachment.

The second intrinsic property of kinship is that it is, by definition, a permanent characteristic of the relation between two individuals. This property, in combination with the first one, means that kinship generates enduring biases in altruism and cooperation between relatives, provided the latter recognize each other as kin and have opportunities of interacting on a regular basis. In other words, kinship is a major source of long-term social relationships. As discussed below, the exact repertoire of kinship bonds found in any species depends on many factors, including which kin live together, whether paternity is recognized or not, and the nature of the criteria used by individuals to differentiate their kin. In nonhuman primates, relationships between kin are limited to those that coreside in the same local group, whereas humans are in a position to maintain relationships with kin living in groups other their own.

Finally, the third property of kinship is that it generates extensive *genealogical structures* within which individuals are connected to each other either lineally or collaterally (definitions below). The interest of genealogical structures lies in their group-level character and hence in their potentially important role in shaping social structure as a whole. Depending on the extent of kin recognition, genealogical structures may translate into *kinship structures*, that is, in consistent patterns of social relationships that map the genealogical structure, such as lineages or clans. If kin living in distinct groups maintain relationships with each other (as in humans), genealogical structures produce multigroup kinship networks.

Kin Recognition Universals

The impact of the three intrinsic properties of kinship on social life depends crucially on which kin are recognized. Humans form

multimale-multifemale groups. Owing to our species' life-history characteristics in terms of longevity, age at sexual maturity, interbirth interval, and other parameters, those groups contain three to five generations of individuals, a configuration that maximizes the diversity of coresident kin types. A description of the domains of kin recognition in other primate species will make it possible to differentiate between shared and uniquely human components and better appraise the magnitude of human kin recognition.

The Evolutionary Background of Human Kin Recognition

The other primate species forming multimale-multifemale groups may be divided into two categories according to their dispersal pattern: *female philopatry* or *male philopatry*. In female philopatric species, females stay and breed in their natal group, whereas males leave around puberty to breed in other groups. This dispersal pattern produces spatially localized and rather extensive, three-generation *matrilines* (the set of individuals descended from a common female ancestor through the female line only) but small *patrilines* (the individuals descended from a common male ancestor through the male line only) because males leave their fathers' group. Reciprocally, in male philopatric species, the males stay put and the females leave, a pattern generating, this time, extensive patrilines but small matrilines. Dispersal patterns thus determine which kin live together and have opportunities of recognizing each other. It should be noted here that the word "recognize" does not mean that nonhuman primates perceive genetic relatedness per se, nor that they necessarily conceptualize kin types; it simply means that they interact preferentially with certain individuals, based on their kinship relations with them. For example, mothers are inferred to recognize their daughters based on the observation that they direct certain types of prosocial behaviors to their daughters (approaches, vocalizations, lactation, ventral and dorsal transport, grooming, protection against aggressors, tolerance at food sites, and so on) at higher rates than they do so with less closely related or unrelated individuals. Kin recognition

thus refers to the differential treatment of individuals belonging to different kin categories.

A few definitions are required at this stage. A *lineal* kinship relationship is a chain of parent-child links connecting two individuals, one of whom is ancestral to the other. The individuals may be related through the maternal line only, e.g., a female to her maternal grandmother (*maternal* kin), or through the paternal line only (*paternal* kin). A *collateral* kinship relationship is a chain of parent-child links connecting two individuals, neither of whom is ancestral to the other, such as siblings, aunts and nieces, and cousins. The *genealogical distance* between two kin refers to the number of parent-child links separating them, for example, two links between a grandmother and a grandchild (lineal distance), and three links between a female and her niece (collateral distance). It is also useful to differentiate between ego's *primary kin* (ego's parents, children, and siblings), *secondary kin* (the primary kin of ego's primary kin, such as ego's grandparents, uncles, and nieces), *tertiary kin* (the primary kin of ego's secondary kin, such as great-grandparents and cousins), *quaternary kin* (the primary kin of ego's tertiary kin, such as second-degree cousins), and so on. Finally, the expression *domain of kin recognition* refers to the set of differentiated kin types from ego's perspective.

Observational and experimental studies indicate that the recognition of maternal kin is widespread and sometimes extensive in nonhuman primates, whereas the recognition of paternal kin is comparatively very limited. In female philopatric species, such as macaques and baboons, a female recognizes a substantial fraction of her coresident maternal kin, including her sisters, brothers, mother, daughters, sons, grandchildren, great-grandchildren, grandmother, great-grandmother, and, less systematically, her aunts and nieces, whereas her cousins and other collateral relatives are treated as nonkin (Chapais 2008). In other words, females recognize their primary kin, some of their secondary kin, but usually not their tertiary kin. The recognition of maternal kin stems from the existence of lifetime bonds between mothers and daughters and

appears to involve primarily familiarity and association-based processes (Rendall 2004). In those species, young females come in contact with their sisters, grandmothers, aunts, and other kin types on a regular basis, thanks to the enduring bonds their mothers maintain with those kin. The mother's mediation sets in motion at least two distinct and complementary processes likely involved in kin recognition (Chapais 2008). First, because the mother spends different amounts of time in proximity with her own mother, sisters, nieces, and so on, her daughter accumulates different levels of developmental familiarity with each of those kin. At the same time, the daughter is in a position to learn the specific characteristics of the relationships her mother maintains with her various relatives in terms of degree of proximity, grooming rates, willingness to protect them against certain individuals, and so on. The capacity of nonhuman primates to recognize the relationships of others is well documented (Seyfarth and Cheney 2012). Importantly, both processes of maternal kin recognition require mothers and daughters to maintain lifetime bonds with each other.

The recognition of maternal kin is also observed in male philopatric species, such as our closest relatives, chimpanzees and bonobos. However, the transfer of females between groups usually limits the domain of kin recognition to primary kin (mother-offspring dyads and maternal siblings) for a male will never meet his mother's kin – they live in other groups – nor the offspring of his emigrated sisters (Chapais 2008; Langergraber et al. 2009). The absence of friendly contacts between groups entails that the recognition of maternal kin is limited to coresident ones (Table 2). For reviews of the influence of maternal kinship on behavior in primates, see Silk (2009), Berman (2011), and Langergraber (2012).

In marked contrast with maternal kinship, paternal kinship is absent or extremely limited in female philopatric species. This is due to two factors. First, males and females have several short-term mating partners (they practice sexual promiscuity) so fathers and offspring cannot recognize each other through the intermediary of an enduring bond between the father and the mother.

Universal Aspects of Kinship, Table 2 The domain of kin recognition in primate species forming multimale-multifemale groups, according to residence patterns and type of kinship

Residence patterns	Maternal kinship	Paternal kinship
Female philopatry in nonhuman primates (e.g., macaques)	Relatively extensive but limited to coresident kin, usually to primary and secondary kin	Absent or very limited owing to sexual promiscuity and male dispersal
Male philopatry in nonhuman primates (e.g., chimpanzees)	Limited to coresident kin, usually to primary kin	Absent or very limited owing to sexual promiscuity
Variable postmarital residence patterns in humans	Extensive (beyond quaternary kin) and includes non-coresident kin	Extensive (beyond quaternary kin) and includes non-coresident kin

However, other mechanisms of kin recognition based on *phenotypic matching* – the capacity to recognize one’s kin based on physical similarities such as odors and physical features between an individual and either self or another kin – may allow individuals to recognize their paternal half-siblings in some species (Widdig 2007; Langergraber 2012). Second, male dispersal in these species entails that males do not grow up with their fathers’ kin and hence have no opportunities of knowing them.

In male philopatric species, by contrast, males do live with their paternal kin and belong to relatively extensive patriline. The available data, however, indicate that paternal kinship is absent or extremely fragmentary in those societies. In chimpanzees, for instance, father-offspring recognition is inconsistent at best (Chapais 2008; Langergraber 2012), which is not surprising given that chimpanzees are highly promiscuous sexually. If individuals cannot recognize their father on a consistent basis, it is unlikely that they recognize their father’s kin, such as their paternal grandfather, uncles, and cousins. Empirical studies also indicate that males do not recognize their paternal half-siblings (Langergraber et al. 2007).

Significantly several of the distinctions made by humans to differentiate their kin are also made by nonhuman primates, though in cognitively much simpler ways, which is precisely what one would expect if the shared criteria had common evolutionary origins. The best way to appraise those criteria in nonhuman primates is to focus on the differentiation of maternal kin in female philopatric species, the context that maximizes the domain of kin recognition (Table 2). Empirical

studies (reviewed in Chapais 2008) indicate that in those species, ego interacts differently with its kin depending on whether (1) ego’s kin is a male or a female; (2) the actor, ego, is a male or a female; (3) ego is younger or older than its kin; (4) ego’s kin belong to an ascending (senior) or descending (junior) generation; (5) the lineal distance between ego and its kin is different; and (6) the collateral distance between ego and its kin is different. The effect of each factor on how ego treats its kin is best appraised when all other criteria are held constant.

The effect of whether ego’s kin is a male or a female is evidenced by the observation that ego interacts differently with its brothers and sisters for in this comparison all other factors are constant: ego’s brother and sister are collateral kin belonging to the same generation, separated from ego by the same genealogical distance, and having similar ages (averaged over many dyads).

The effect of ego’s sex on how ego treats its kin is illustrated by differences in how a male and a female interact with a sister, in which case, the two dyads (brother-sister and sister-sister) are collateral kin that belong to the same generation, share the same genealogical distance, and have similar age differences on average.

Differences in how a female interacts with a younger sister and an older one illustrate the effect of ego’s age relative to its kin. In this situation, the two types of sister dyads are collateral kin of the same sex belonging to the same generation and sharing the same genealogical distance.

Differences in how an adult female interacts with her mother and her daughter shows that she differentiates between individuals belonging to an ascending (senior) or a descending (junior)

generation. To ego, both individuals are lineal kin of the same sex and same genealogical distance. They differ in age, however, which makes it possible that ego's differential treatment might reflect the effect of age rather than generation. This is highly unlikely, however, given that ego has a filial relationship with her mother and a parental one with her daughter, which points to the effect of generation per se.

The effect of genealogical distance between lineal kin is exemplified by differences in how females interact with their mother (one parent-child link) and with their grandmother (two links) and by differences in how they interact with their daughter (one link) and granddaughters (two links). To ego, all those individuals are lineal kin of the same sex. But note that those behavioral differences may also reflect the effect of belonging to an adjacent or a nonadjacent generation in relation to ego (whether ascending or descending).

Finally, the effect of genealogical distance between collateral kin is exemplified by the observation that females have much higher rates of prosocial behavior with their sisters than with their female cousins. From ego's perspective, sisters and cousins are collateral kin belonging to the same sex, generation, and age group, but while sisters are separated from ego by two parent-child links, cousins are by four links.

Importantly, the fact that those factors affect how nonhuman primates interact with their kin does not imply that animals conceptualize sex, relative age, ascending versus descending generations, lineal distance, and collateral distance. It means, minimally, that they use proxies, behavioral and/or phenotypic, that correlate with those factors.

Kin Recognition in Humans

The domains of kin recognition in humans are much more extensive compared to the situation in other primates. They include both maternal and paternal relatives and extend to quaternary kin and beyond (Table 3). This reflects essentially three factors. First, the existence of stable reproductive bonds, whether monogamous or polygynous, allows father and offspring to recognize each other based on their enduring relationship with

the same female – wife to one, mother to the other. This in turn allows individuals to recognize their father's kin and their brother's children. In short, kin recognition is bilateral (bilineal), a uniquely human phenomenon.

Second, kin recognition is independent of whether relatives live in the same group – are coresident – or not, because contrary to the situation in other primates, dispersal from the natal group (i.e., a change of residence at marriage, what anthropologists call *postmarital residence*) does not bring about the end of contact between spatially dispersed kin; the latter keep visiting each other on a regular basis (Rodseth et al. 1991). As a result, ego's actual kinship network includes individuals born and living in other groups. Another important consequence of intergroup visiting is that cross-sex kin, such as fathers and daughters and brothers and sisters, are in position to maintain lifetime bonds with each other. This is usually not possible in other primates forming multimale-multifemale groups because dispersal is strongly sex biased and cross-sex kin cease to interact with each other after they have left their natal group. Intergroup visiting, intergroup kin recognition, lifetime bonds between cross-sex kin, and multigroup kinship networks are uniquely human, cross-culturally universal phenomena. They are also highly consequential ones considering that some classic chestnuts of the anthropology of kinship such as *cross-cousin marriage* (unions between the children of cross-sex siblings), and *avuncular relationships* (special relationships between men and their sisters' sons) require lifetime bonds between cross-sex kin (Chapais 2008, 2014).

Third, thanks to enhanced cognitive abilities, humans differentiate their kin on the basis of a much larger set of criteria and distinctions compared to other species (Table 3). As primates, humans inherited the capacity to recognize their kin based on their degree of developmental familiarity with them and on how their parents interact with different kin. In that vein, the close association between newborns and their mother was found to operate as a specific cue allowing individuals to recognize their younger siblings (Lieberman et al. 2007). Phenotype matching

Universal Aspects of Kinship, Table 3 *Kin recognition universals* classified in relation to four dimensions

Dimensions	Kin recognition universals
Mechanisms of kin recognition	Developmental familiarity with one's kin
	Differentiation of bonds between one's mother and other kin
	Recognition of facial similarities between one's kin
	Recognition of facial similarities between self and kin
	Naming kin
Factors defining domain of kin recognition	Multimale-multifemale groups
	Multigenerational groups
	Stable breeding bonds (father-child recognition)
	Dual-phase residence (pre-/postmarital)
	Exogamy (outmarriage)
	Sex-biased or bisexual postmarital group transfer
	Sex-biased or bisexual postmarital residence
	Postmarital residential variability across groups
	Postmarital residential flexibility within groups
	Intergroup visiting
	Multigroup, multilevel social organization
Domain of kin recognition	Mother-offspring recognition
	Father-offspring recognition
	Recognition of lineal kin
	Recognition of collateral kin
	Recognition of maternal kin beyond quaternary kin
	Recognition of paternal kin beyond quaternary kin
	Recognition of deceased ancestors
	Matrilineal descent (chains of mother-daughter links)
	Patrilineal descent (chains of father-son links)
	Recognition of lineages as entities
	Intergroup kin recognition (i.e., independent of coresidence)
	Lifetime bonds between same-sex kin
	Lifetime bonds between cross-sex kin
	Recognition of kin's spouses (affines)
	Recognition of spouses' kin (affines)
	Recognition of affines independent of coresidence
	Symmetrical recognition of affines (husband's and wife's)
Classification of kin	Kin terminologies
	Classificatory kinship
	Criteria of kin differentiation (minimal)
	Ego's sex
	Kin's sex
	Relative age of kin
	Ascending versus descending generation
	Lineal distance
	Collateral distance
	Lineal versus collateral kin
	Bifurcation

also seems to be at work. Humans are proficient at recognizing physical similarities between kin (e.g., between fathers and their children), including similarities between their own kin, for example, their mother and the latter's sisters. They also appear to recognize similarities between themselves and their kin. Experimental research using computer-graphic software to create images of individuals resembling the participants reveals that humans perceive their "virtual siblings" as more trustworthy than other individuals (DeBruine et al. 2011; for a review of the psychology of human kin recognition, see Park et al. 2008). To those association-based and phenotypic matching mechanisms, the evolution of symbolic communication superimposed the capacity to learn about one's kin based on how these are labeled, no doubt a major step in the extension of the domain of kin recognition among hominins (Jones 2010).

Language-based kin classifications and terminologies are cross-culturally universal (Fox 1967), and, importantly, they translate into the differential treatment of kin types: ego has different kinds of social interactions, rights, prerogatives, and obligations with the members of different kin categories. Anthropologists have documented a large variety of kin terminologies, which they group into a number of broad types – e.g., Hawaiian, Iroquois, Eskimo, Crow, Sudanese, and Omaha – depending on which kin types are differentiated and labeled accordingly or grouped together under the same label. For discussions of kin terminologies and of the principles regulating the observed diversity, see Goodenough (1970), Hage (1997), Kronenfeld (2006), and Jones (2010).

Despite their high degree of diversity, all kin terminologies appear to stem from the same set of universal, often binary, criteria (Table 3), a fact implying that variation reflects different ways of using the same criteria in different cultures. As pointed out earlier, humans make distinctions similar to those made by other primates but with some notable differences. Because we conceptualize those distinctions – that is, because we have concepts about "generation," or "lineal kin" – we may group together several distinct kin types on

the basis of a particular criterion (e.g., membership to the senior generation from ego's perspective), irrespective of several other criteria such as genealogical distance, age, and sex. This is called *classificatory kinship*. Kin terminologies vary markedly in this respect. For example, some terminologies group and label accordingly all members of an ascending generation in relation to all members of a descending one, whereas other terminologies distinguish between kin belonging to odd generations in relation to ego (parents and children) and kin belonging to even generations (grandparents and grandchildren). For a given criterion, humans make finer distinctions compared to other primates. For instance, some kin terminologies take generation distance into account and label differently the members of the first, second, third, fourth, and fifth generation, without regard to sex and ascending versus descending generation (Goodenough 1970). As another example, with respect to collateral distance, many societies differentiate between first-degree, second-degree, and third-degree cousins.

Not only do humans conceptualize the criteria they share with other primates, they also utilize at least two additional ones, namely, whether they are related to an individual through a male or a female and through a marital tie or not. Anthropologists use the term *bifurcation* to refer to the fact that humans classify their kin according to whether they are related to an individual through the mother (maternal relative) or the father (paternal relative). This allows distinctions between mother's brothers and father's brothers, patrilineal and matrilineal cousins, and so on. Bifurcation is not possible in other primates forming multimale-multifemale groups if only because, as we saw, sexual promiscuity prevents systematic father-offspring recognition so that individuals are not in a position to recognize their paternal relatives. This suggests that the bifurcation criterion became operative among hominins only after the evolution of pair-bonding and paternity recognition.

Humans also take into account whether they are related to a kin through a marital tie or not. Anthropologists use the term *affines* (in-laws) to refer to the spouses of one's kin and the kin of

one's spouse. A husband's affines comprise the spouses of his own kin, such as those of his children (daughters- and sons-in-law) and siblings (brothers- and sisters-in-law), and his wife's relatives, such as her parents (father- and mother-in-law) and siblings. The same applies to the wife, who recognizes both the spouses of her kin and her husband's relatives. The recognition of affines is thus symmetrical. Depending on cultures, humans may make several finer distinctions. They may, for example, label affines differently depending on the number of marital ties separating them from ego, whether that number is odd or even, whether the marital ties belong to a junior or senior generation, and so on (Goodenough 1970). Because *exogamy* (marrying out of one's group) is the rule in humans, many of ego's affines reside in groups other than ego's group. The symmetrical recognition of affines thus requires intergroup visiting, which explains why affinal kinship is uniquely human.

Finally, humans recognize deceased kin, including their ancestors, notably because they are told about their existence. This was a prerequisite for the recognition of chains of mother-daughter links including dead female ancestors (*matrilineal descent*) and chains of father-son links including deceased male ancestors (*patrilineal descent*). The recognition of descent in turn was an integral part of the recognition of matriline and patriline as social entities, that is, as entities whose members, by virtue of descent from a common, recollected ancestor, share a number of prerogatives, rights, and duties. Prior to the advent of humanlike conceptualization, matriline and patriline were primate-like patterns of social relationships mapping genealogical structures. With conceptualization, matriline and patriline evolved into *matrilineages* and *patrilineages*, in the anthropological sense of the term: kinship structures recognized as such and constituting political and economic units (e.g., Stone 2014).

Relational Kinship Universals and Their Consequences

Relational kinship universals are defined here as universal characteristics of specific categories of

kinship bonds. As pointed out earlier, the permanent character of kinship links favors the development of enduring social bonds between relatives. Some categories of kinship bonds are found in all cultures even though their exact form and content vary substantially across cultures. Such is the case with relationships between primary kin (parents, children, siblings) and some secondary kin, for example, grandparents and grandchildren. Relationships between more remote kin are often not universal owing to cultural variation in classificatory rules.

Kinship bonds belonging to the same universal category, such as parent-child bonds and sibling bonds, share a number of commonalities or relational kinship universals. Although those panhuman features of kinship bonds necessarily have a general character, their interest lies in the magnitude of their impact on human social life. In fact, much of the *deep structure* of human society – the set of structural principles common to all human societies (Chapais 2008) – stems from the universal characteristics of kinship bonds. Parent-child relationships, perhaps the most consequential of these, will serve to illustrate the idea.

Human children all over the world share the same basic set of needs in terms of physical, emotional, cognitive, and social development. Similarly, all human parents are equipped with the same basic morphological, emotional, and cognitive adaptations to satisfy those needs. This translates into the existence of a universal set of parental propensities toward children. Children needs, however, are not sufficient to apprehend the full scope of parental propensities. One must also take into account the fact that humans have the capacity to exercise *instructional control* over others (Chapais 2014). Compared to other animals, humans are able to orient the behavior of other individuals by telling them what to do and not to do. Among the most important cognitive abilities underlying instructional control are language, which makes it possible to spell out directives, and *theory of mind*, the capacity to know that others have thoughts and beliefs of their own. Other primates lack language and a full-blown theory of mind (Call and Tomasello 2008) so the control of others is noninstructional and limited to

preventing others from doing certain things. After the cognitive underpinnings of instructional control had evolved among hominins, individuals could attempt to orient the thoughts and behavior of others either to satisfy their own self-interest or to help their friends and relatives. The parent-child relationship lent itself particularly well to instructional control given the high degree of physical, emotional, and economic dependence of children in relation to parents.

Table 4 gives a sample of universal parental propensities in humans, the last three of which exemplify the possibility for parents of orienting the behavior of their children in ways that satisfy the parents' own interests independently of whether their children agree or not. It is not assumed here that each propensity has its own dedicated biological mechanism or constitutes a Darwinian adaptation. A parental propensity is rather seen as the emergent product of a number of more elementary components which are themselves universal. These include the three intrinsic properties of kinship previously discussed, the cognitive underpinnings of instructional control, the relevant needs or opportunities underlying the propensity (first column in Table 4), and the fact that the parental response in each type of context benefits parents either directly (personal fitness) or indirectly (inclusive fitness). The reasoning also rests on the assumption that universal propensities are so basic as to be internally generated (individually learned by all parents placed in

similar circumstances). In other words, parental propensities would be intuitive components of parental care rather than cultural inventions – even though the particular expression of any propensity is culturally determined (see Chapais 2016).

The relational universals of parent-child relationships appear to have played a central role in defining the deep structure of human society. For example, the propensity to provision children late into adolescence lies at the origin of the division of labor between parents and of the organization of domestic activities in general. Indeed if it were not for the importance of the costs of raising highly dependent children, mothers and fathers would probably not have been selected to form cooperative partnerships in the context of subsistence activities and hence would not have specialized in different ones. Although the exact form taken by the sexual division of labor is extremely variable across foraging, pastoral, agricultural, and industrial societies, the specialization principle is universal, has deep evolutionary roots visible in chimpanzees (Chapais 2011), and appears to reflect the advantages of dividing tasks between partners, compared to accomplishing similar ones (Gurven and Hill 2009). Sexual specialization in turn is a foundational principle of human social organization.

As another example, the parental propensity to transmit material possessions to children, either during the parents' lifetime or at death, lies at the very foundation of heredity-based social orders or

Universal Aspects of Kinship, Table 4 A sample of *relational kinship universals* pertaining to the human parent-child bond

Universal needs and opportunities afforded by children	Corresponding parental propensities (relational universals)
Environmental threats	Protection against physical threats
Intra and intergroup conflicts	Protection against social threats
Lengthened period of dependence	Long-term provisioning of children
Complex technical environment	Transfer of technical knowledge
Complex social environment	Transfer of social knowledge
Complex ideational environment	Transmission of beliefs
Dependence on material possessions	Transmission of possessions (inheritance)
Conflicts between siblings	Interventions in siblings conflicts
Cooperative nature of subsistence activities	Inducing children to contribute to subsistence
High costs of raising children	Inducing children to take care of their siblings
Selection of marital partner	Orienting children's mate choice

hereditary succession. The transgenerational inheritance of wealth and status among lineal kin is observed in societies in which there is material wealth to be accumulated and transmitted, where it generates various forms of heredity-based socioeconomic stratifications, but is much less salient in many foraging societies where differentials in wealth are much weaker or virtually absent (Borgerhoff Mulder et al. 2009).

A final illustration of the role of relational kinship universals in defining human society concerns the parents' propensity to orient their children's choice of a marital partner. This propensity is perhaps the most basic aspect of the widespread phenomenon of matrimonial exchange (Chapais 2014). Cross-cultural studies indicate that *marital arrangements* – agreements between families about the formation of marital unions – are the rule in hunter-gatherer (Apostolou 2007), horticultural, agricultural, and pastoral societies (Apostolou 2010). Marital arrangements take various cultural forms – sister (or daughter) exchange, prescribed marriages between cross-cousins, levirate (a widow marrying her husband's brother), sororate (a widower marrying his wife's sister), and bride service (service rendered by the groom to the bride's family). However diverse, all forms of marital arrangements share a number of fundamental properties: they are planned and regulated by parents and hence imply the instructional control of children; they are governed by the principle of conditional reciprocity; and they rest on the high value of children as commodities of exchange, a value reflecting the importance of securing a competent spouse in a species in which reproduction involves high levels of parental investment and spousal exchange generates long-lasting alliances between families.

Marital arrangements thus depend crucially on the parental propensity to orient mate choice. But for that propensity to translate into children exchange, two conditions must be met (Chapais 2014): parents must benefit from exchanging children, which appears to be the case in a vast number of societies in which children exchange is a primary means of obtaining spouses, resources, services, and alliances (Apostolou 2007, 2010),

and parents must be in a position to impose their preferences to children, a condition often met in preindustrial societies, where children are economically dependent on their parents, but often not satisfied in Western societies, where children may be financially independent of their parents at an earlier age. When the socioecological context is favorable, parents take control of mate selection, and as result, families become dependent on each other for obtaining spouses; they have no choice but to exchange children.

Conclusion

Throughout the present review, the emphasis has been placed on the universal aspects of kinship, but, as just discussed in relation to the role played by relational universals in generating heredity-based stratifications and marital arrangements, kinship universals help crucially in understanding social phenomena that are *not* cross-culturally universal. The same principle applies to many other social patterns exhibiting a strong kinship component, some of which are secular topics of the anthropology of kinship (e.g., unilineal descent groups, lineage segmentation, avuncular relationships). Universal kinship components are an integral part of each such phenomenon, but because they always interact with many other cultural variables, the outcome is a great deal of cross-cultural diversity. Thus, the interest of universals lies not only in their universality per se as in the role they play as “biological constants” involved in the regulation of highly variable social patterns. Universals are to cross-cultural variation what constants are to mathematical equations: essential components of models and theories purporting to explain variation.

Universal Grammar

Jason Brown

Faculty of Arts, University of Auckland,
Auckland, New Zealand

Synonyms

Mental grammar; UG

Definition

The innate mental structures that constitute the language faculty in humans.

Introduction

Under the view originally presented by Chomsky (1965), all languages have gross commonalities, even though there exist differences across languages. For instance, all languages have predicates and arguments, and all languages have nouns and verbs. There are also similarities in the realm of syntax, such that languages tend to place the verb and its complement object in a consistent order, though this order is subject to variation across languages. As an example, English exhibits a Subject-Verb-Object constituent order, while Japanese opts for a Subject-Object-Verb order. The relative order of Verb-Object or Object-Verb is due to a parametric choice available to languages. In addition to these parameters that yield differences across languages, Chomsky (1965) claims that there are a set of innate, inviolable principles. These are the components of what Chomsky calls *Universal Grammar*, or UG for short.

The Role of UG in Language Acquisition

The innate principles of Universal Grammar come into play in the process of the child's acquisition of language. It is obvious that certain aspects of

language can be learned from positive evidence, i.e., structures that are present in the ambient language and which the child has access to. For example, individual lexical items must be learned from positive evidence alone. There are, however, certain syntactic structures which exist in languages, but which cannot be learned from positive evidence. These are cases where the child has knowledge about forms that are *ungrammatical* in the language they are acquiring. A prime illustration is the oft-cited example of the coordinate structure constraint (Ross 1967), which prevents questions from being formed by means of the fronting of only one element of a coordinate structure. For example, while "What did you eat your eggs with?" is a licit structure in English, *"What did you eat your eggs and?" is ungrammatical. No child ever produces forms such as the latter at any stage of acquisition. Furthermore, despite the lack of positive evidence (i.e., children never have access to examples of these sentences), children still manage to acquire the ambient language, including the knowledge that coordinate structure constraint violations, and other such structures are ungrammatical. This is presumably a universal cross-linguistic constraint, and it is presumably an innate part of Universal Grammar. This lack of positive evidence is what Chomsky (1980) terms *the poverty of the stimulus*, and what Chomsky (1988) relates to "Plato's problem." Since the child accurately arrives at the correct structures, Chomsky has argued, it must be the case that there are mechanisms that are innate to the child.

Bickerton (1981) has presented evidence that indicates that much the same argument can be applied to creole languages. Creoles are the product of language contact and are not grammars inherited entirely from a single source. Instead, a superstrate and a substrate language are essentially combined into a pidgin – a lingua franca that is grammatically simpler than either of its parent languages. The relative simplicity of pidgins is due to their limited usage, mostly as trade languages. Children who acquire the pidgin as a first language, though, have been observed to provide it with highly structured grammatical scaffolding. The result is a creole, which has a fully developed grammatical system. Bickerton

demonstrated that elements of these grammars must emerge *sui generis*, as there is no positive evidence in the learning environment for these structures. It is presumably Universal Grammar which endows the child with the necessary components to provide this structure to the grammar.

Conclusion

Recent thought in grammatical theory is that Universal Grammar is a human genetic endowment that is inherited (Hauser et al. 2002; Chomsky 2007). Given this biological foundation, this recent approach is often termed “biolinguistics” (though the term is much older). Current thinking is that there is a single syntactic operation, called *Merge*, and that this operation serves as the foundation for Universal Grammar, including its evolutionary beginnings. Contemporary approaches to Minimalist syntax (cf. Chomsky 1995) are dedicated to exploring these issues.

Definition

A distressing emotion caused by anticipation or awareness of danger.

Introduction

Darwin states, in his book *The Expression of the Emotions in Man and Animals* which supported the theory of natural selection, that fear is “the most depressing of all the emotions” (Darwin 1872, p. 36). A century later, basic emotion theorists have proposed that certain emotions are innate, in part because they are expressed the same in people around the world (e.g., Ekman 1977). There is growing agreement among researchers that fear is an adaptive emotion that motivates “fight or fly” behavior, ultimately promoting self-protection. This entry is focused on (1) domains of human fear and (2) preparedness learning, (3) perceptual biases, and (4) gender differences to support its evolutionary origin.

Fear is associated with ancient parts of the brain; the amygdala areas, which are located deep and medially within the temporal lobes of the brain, have been involved in fear conditioning in a variety of mammals, including rats, mice, rabbits, and monkeys (for a review, see LeDoux 2012). Almost universal physiological and behavioral responses to fear-related stimuli are escape, avoidance behavior, a stronger heart rate, blood pressure, respiration, and adrenaline and glucocorticoid release. It is suggested that fear-related

responses are adaptive, because they prepare our bodies for a fight or escape from a potential danger. Both types of responses require accelerated metabolism via glucose release by adrenaline and oxygen supply to the muscles by rapid breathing in order to make energy available to the muscles for fight or flight (Marks and Nesse 1994).

Evolutionary psychologists have suggested that fear has developed for mostly ancient threats (e.g., certain animals such as snakes, spiders and rats, heights, storms, darkness, blood, strangers, and separation or leaving the safety of home), but not to current threats (e.g., cigarettes, cars, electrical equipment, or handguns). Three lines of evidence support this idea. First, fear stimuli are nonrandomly distributed and are related to real (albeit ancient) threats (Marks and Nesse 1994). People rarely display, for example, a fear of trees, stones, or the sky which were not harmful to our ancestors, but fears of harmful objects or events are relatively common. Second, Martin Seligman (1971) has proposed that fears reflect evolutionarily prepared learning to fear events and situations that have provided survival threats in our evolutionary past. This can be documented with classic experiments carried out by Cook and Mineka (1990, 1991). Laboratory-reared, but not wild, monkeys do not manifest strong fearful responses to snakes suggesting that their reactions are learned, rather than innate. Monkeys are, however, able to quickly acquire a fear of a predator by observing other monkeys expressing fear in interaction with the predator. When laboratory-reared monkeys observed a wild-reared monkey displaying fear of a live and toy snake, they were rapidly conditioned to fear snakes (Cook and Mineka 1990). In consequent experiments, the laboratory-reared monkeys observed displays of fear in response to toy snakes (predators) and flowers (harmless objects) or to toy crocodiles (predators) and rabbits (harmless objects). Fear responses were conditioned only for predators, but not for flowers and toy rabbits (Cook and Mineka 1991). Since the laboratory-reared monkeys had no previous experiences with the stimuli used in the experiment, these results provide support for an evolutionary basis to the prepared learning (Öhman and Mineka 2001).

Third, common human fears seem to develop at a time when the danger might be encountered. Fears of heights and strangers, for example, emerge in infants at about 6 months of age, when infants begin to crawl away from their mothers thereby increasing the risk of a fall and/or kidnapping. The higher risk of an infant being killed by strangers has been documented both in nonhuman primates as well as in modern humans. At the age of 2 years, when infant exploration begins to be more intense, animal fears and fear of darkness emerge (for a review, see Gullone 2000). Humans, unlike nocturnal animals, have limited vision making them more vulnerable to predators when their visual capacity is limited. Fear of the dark restricts infant mobility thereby decreasing vulnerability to predators. Later, when the young child leaves the home base, agoraphobia, the fear of being in crowds or public places, which makes escape difficult, may develop (Marks and Nesse 1994). The intensity of fears in children tend to decrease with age (Gullone 2000) which can be explained by their higher physical and emotional independence from parents.

Evolutionary Evidence for Fear of Dangerous Animals

Snakes are viewed as prototypical stimuli of common fears of animals (Öhman and Mineka 2001). Snakes are present on all continents except Antarctica, and their putative fossils date back as far as 150 million years. At this time, constrictor snakes were critical predators of the small ancestors of modern placental mammals (Isbell 2009). Note that carnivore predators occurred much later, only about 40–60 million years ago. Transitional primate-like creatures were evolving ca. 65.5 million years ago, and recent primates are still attacked by snakes (Cook and Mineka 1991). This evidence suggests that the evolution of primate defense against predators was influenced by snakes.

The second line of evidence regarding danger from snakes comes from introducing an effective venom – a new powerful weapon in the

predator–prey arms race with primates. Fossils of snakes with venomous fangs from at least the Lower Miocene have been discovered, i.e., far before the first ancestors of *Homo* appeared. This evidence strongly suggests that interactions between snakes and early humans could be expected. Snake bite caused substantial human mortality and disability, although these issues have been largely neglected by health organizations. It is estimated that snake bites cause roughly about 20,000–125,000 deaths worldwide, although these estimates are based on incomplete data (Warrell 2010), partly because reporting is not mandatory in many regions of the world. It can be suggested that snake mortality was much higher in our evolutionary past, when human interaction with nature occurred daily and medical help was highly limited (if any).

The early coexistence of dangerous snakes with their mammalian prey may be the reason why snakes are frequently sources of phobias. Robins and Regier (1991), for example, determined that “bugs, mice, snakes or bats” were the most frequently cited category of phobic fears. Indeed, snakes are traditionally labeled as the least liked animals in a range of surveys on animal fears, while certain other terrestrial predators such as wolves or bears received more positive rankings by people (Schlegel and Rupf 2010; Almeida et al. 2014).

Threatening Objects Promote Visual Attention

Coevolution with snakes as significant primate predators predicts that primates, including humans, should have developed a specific visual sensitivity for snake (i.e., danger) cues that promotes vigilance for an early detection of stimuli to escape and/or avoid potentially a deadly encounter with the predator and hence survive and reproduce (Öhman et al. 2001a). Neurobiological research supports this idea, because amygdala tunes visual brain areas for rapid perception of fear-related stimuli. Furthermore, it seems that specific neurons in the primate brain respond especially quickly to images of snakes (Van Le et al. 2013). Humans, similarly to nonhuman

primates, seem to have no innate fear of snakes (DeLoache and LoBue 2009), but show similar abilities to condition snakes with something fearful (LoBue and DeLoache 2010). Rakison and Derringer (2008) found, for example, that 5-month-old infants look longer at a schematic image of a spider or a snake relative to scrambled versions of the same schematic image and look equally long at nonthreatening images such as flowers.

To support the rapid detection of snakes relative to other non-treating stimuli, Öhman et al. (2001a) compared the detection of a fear-relevant target (a snake or a spider) among eight fear-irrelevant distractors (flowers or mushrooms) with that of a fear-irrelevant target (a flower or a mushroom) among fear-relevant distractors (snakes or spiders). As expected, snakes and spiders were detected more quickly than flowers and mushrooms. These findings were repeatedly reported in a number of studies, involving both children and adults (for a review, see LoBue and Rakison 2013). It can be argued that humans should also be sensitive to a visual detection of the emotional cues in the faces of other members in the social group because significant numbers of violent deaths can be attributed to conflicts between conspecifics – similarly as with chimpanzees. The same paradigm suggesting that fear-relevant stimuli receive rapid detection in order to avoid potential threat, Öhman et al. (2001b) found that threatening faces are detected by humans among neutral faces more quickly than friendly faces, a finding which was successfully replicated by other researchers (for a review, Öhman et al. 2001b; LoBue and Rakison 2013). These findings suggest that there is a clear bias for threat in visual detection tasks.

Gender Differences in Common Fears

Girls exhibit more fears than boys (Arrindell et al. 2003), and at least some of them can emerge very early (Rakison 2009). In particular, girls reported being more fearful of darkness, strange sights and sounds, loneliness, personal relationships, animals, injury, and being kidnapped, robbed, or killed (Gullone 2000; Arrindell

et al. 2003). Boys reported being more fearful of not being good and getting into trouble, nightmares, and imaginary creatures including monsters, gorillas, and dinosaurs (for a review, see Gullone 2000). Gender socialization experiences may contribute to the reporting of fear difference by males and females. Girls may learn that it is permissible to express fears, whereas boys are expected to inhibit fears. Rakison (2009) found, however, that 11-month-old female but not male infants learn rapidly to associate negative facial emotions with fear-relevant stimuli (snakes and spiders) suggesting that socialization need not to be the key factor responsible for gender differences in fearfulness.

Although gender differences in fears were reported in a number of studies, their evolutionary origin is much less clear. Certain researchers have suggested that a higher fear of large carnivore predators in females can be explained by female's lower physical condition compared with the physical condition of males (Røskaft et al. 2003; Prokop and Fančovičová 2013). Indeed, females and children who are physically weaker than males are less likely to survive predatory attacks of large carnivores (Treves and Naughton-Treves 1999). The disease avoidance hypothesis suggests that vulnerability to infectious diseases makes people more sensitive to a potential danger. Indeed, females are more disease vulnerable than males, and more disease-vulnerable people perceive animals as more dangerous than less disease-vulnerable people (Prokop and Fančovičová 2013). These two hypotheses can be viewed as compatible, because disease vulnerability is associated with a poorer perceived physical condition (Prokop and Fančovičová 2013). The parental investment hypothesis proposes that females take care of children and have to be more sensitive to danger in order to protect their offspring (Røskaft et al. 2003). This hypothesis has not received empirical support as yet.

Why Humans Display a Fear of Harmless Stimuli

About 100 years ago, John Watson demonstrated that an infant (9-month-old Little Albert) can be

conditioned to fear a white rat by pairing the presentation of the rat with a loud aversive noise. Upon seeing the rat, Little Albert became extremely distressed, crying and crawling away. Interestingly, Little Albert's fear was later generalized to the sight of several other furry objects, such as a rabbit, a furry dog, and a sealskin coat and even a Santa Claus mask with white cotton balls in the beard. It was later proposed of course that classic conditioning is not the only way one acquires fear. Observations, verbally transmitted information, and some other mechanisms (LoBue 2013) can also develop fear.

This simple example of Little Albert's generalization of fear may explain why humans manifest a fear of certain fear-irrelevant stimuli: harmless snakes (Arrindell et al. 2003) or worm-like invertebrates (Schlegel et al. 2015) are considered dangerous or unlikeable, although they do not pose an actual danger. All of these stimuli are associated with potentially dangerous cues, because they superficially look like dangerous animals. The superficial perception of potentially harmful stimuli is favored by natural selection in order to minimize the likelihood of failing to register the presence of genuine danger (the smoke detector principle, Nesse 2005). Although the avoidance of harmless snake could be perceived as "erroneous" (false-positive error), it is still less risky than erroneous detection of a truly harmful snake (false-negative error). That is, predictions guided by the evolutionary theory do not propose that all fears should have reasonable explanations in our ancestral past, but that certain fears can also stem from similarities with fear-relevant stimuli. Finally, some fears are conditioned in everyday life. Children can, for example, easily acquire fear of a medical doctor simply because pain from vaccination is associated with the doctor. The same mechanism can be applied to dogs showing a fear of veterinarians.

Conclusion

The protective emotion of fear was highly beneficial in the ancestral environment where it evolved. Modern society, where the risk of being attacked by a predator is low, may perceive certain fears as

irrational, but a better understanding of our evolutionary past would seem to be helpful in reaching an understanding of our emotions. Comparative research on nonhuman primates and human infants where socialization is minimal seems to be promising in uncovering the origins and adaptive functions of common fears.

Definition

Human sex differences in spatial abilities are predicated – in many adaptationist accounts – on males having been subjected to greater selection pressures in one or more domains (e.g., hunting, warfare, mating) to travel extensively throughout unknown territory. Some aspects of extant sex differences – especially in the types of spatial representations and navigational strategies favored by males – may reflect the distinct challenges of traversing large and unfamiliar regions.

Introduction

Many of the adaptationist accounts for sex differences in spatial abilities are motivated by the purportedly greater needs of males than females to travel extensively and through unknown territory. Such accounts differ primarily in their emphasis on which domain of ancestral activities (e.g., hunting, warfare, mating) required males to travel more and consequently greater spatial abilities (Jones et al. 2003). In hunter-gatherer societies, men do commonly have larger home ranges (Ecuyer-Dab and Robert 2004), and their individual success in such fitness-relevant activities has been related to the extent of their travels in some contexts (e.g., Vashro and Cashdan 2015). These adaptationist theories readily anticipate that men's needs to travel more would have selectively enhanced their general abilities to efficiently navigate their larger home range.

Navigating Unfamiliar Areas

It is commonly inferred that males not only traveled more within a large and familiar home range but also ventured more frequently outside their home range into less-familiar – if not entirely unknown – territory. During these longer trips into unfamiliar territory, navigational accuracy would have been even more critical; over greater distances, even small heading errors can compound quickly into large diversions off course. Moreover, the risk of losing one's way in unfamiliar territory is even greater in areas where geographical information cannot be used for course corrections. When moving further from one's home range, established routes between known destinations are soon left behind, and the availability of landmarks for orienting and confirming one's course decreases quickly.

Males' purportedly greater travels in unfamiliar territory may have also been selected for their favoring of navigational strategies that are less reliant on the use of proximal geographical information – in addition to their greater abilities at some basic spatial tasks (Halpern 1992). Males typically employ bird's eye, termed survey,

representations of their spatial environment that are particularly well-suited for navigating new and unfamiliar areas. Further, men prefer to navigate according to cardinal directions, distal landmarks (e.g., mountains), celestial cues (e.g., sun position), and physical distances – strategies that do not rely on environmental information such as proximal landmarks (e.g., water springs) or designated routes (Dabbs et al. 1998; Lawton 1994). These navigational strategies may have proven optimal for pursuing the hypothesized objectives of large game, mating opportunities, or aggressive encounters outside of one's home range. Such ventures would routinely involve their navigation of unfamiliar territory over new, extensive, and wandering paths, while maintaining a sense of relative position to their origin and encountered locations of interest (Dabbs et al. 1998).

Females, however, favor navigational strategies that are heavily reliant on knowledge about their surroundings – particularly the use of routes that are designated, step-by-step, with respect to landmarks for changing or confirming course direction (Lawton 1994). Although route-based navigation is effective for smaller-scale trips, the requisite knowledge and processing requirements grow proportionally – perhaps challengingly so – with increasing distance (Gaulin and FitzGerald 1986). In unfamiliar territories – where fewer proximal landmarks are identifiable – route-based navigation can be considerably less applicable (Ecuyer-Dab and Robert 2004). Whereas males favor navigational strategies that support travel over larger-scale and unfamiliar territory, females favor route-based navigational strategies for which the effectiveness diminishes with increasing distance and decreasing geographical familiarity.

Most evolutionary theories for sex differences in spatial abilities have focused on males' purported needs for greater spatial abilities and strategies to support their navigation through greater and unknown territory (Jones et al. 2003). However, other theories have conversely proposed that female's spatial abilities and preferred navigational strategies reflect their greater needs for navigating smaller and more familiar territorial ranges. In the sexual division of labor hypothesis, women are presumed to have met their nutritional needs

predominantly by gathering immobile plants and capturing small game – activities more proficiently conducted within familiar areas and by revisiting particular locations (e.g., game traps and fruiting trees; Silverman and Eals 1992). The fertility and parental care theory proposes that the greater dependence of offspring on the well-being and parental efforts of the mother acted selectively to contract females' home ranges and decrease their travels into unknown territory during critical reproductive periods (Ecuyer-Dab and Robert 2004). Females' disinclinations for using long-range navigational strategies have putatively functioned to demotivate their traveling extensively and into unknown territory – reducing their exposure to the great risks and energetic expenses of such travels. A number of other influences such as females' lower confidence in their navigational abilities (Picucci et al. 2011) and greater anxiety about navigating (Lawton 1994) and becoming lost (Bryant 1982; Lawton 1994) have also been suggested to deter their travels into unfamiliar territory (Ecuyer-Dab and Robert 2004).

Conclusion

Some of the few reliable sex differences in cognition appear in the domains of spatial reasoning and navigation. The development of these sex differences undoubtedly reflect, to varying degrees, substantial biological and sociocultural factors. However, several distal, originating causes for these differences have been advanced in evolutionary accounts – most of which largely implicate either ancestral differences in women's and men's reproductive roles and strategies or in their primary foraging activities. In many of these accounts, selective pressures functioned to incline males inherently toward larger home ranges and/or to incline females toward smaller home ranges. The needs of males to navigate larger – but familiar – home ranges accounts could have driven some general elaborations and/or enhancements of their spatial abilities. However, selection pressures that were likely far more impactful on males – such as those involved in hunting and

warfare – would have required males to not only travel more extensively, but into unfamiliar and potentially hostile territory. Their needs for venturing into, and returning expeditiously from, unknown areas may have driven further modifications to males' spatial abilities – particularly their preferences for navigational strategies (e.g., survey representations, cardinal directions) that are best-suited for traversing larger and unfamiliar territory.

Unobservability Hypothesis, The (Vonk and Povinelli, 2006)

Jennifer Vonk
Oakland University, Rochester, MI, USA

Definition

The unobservability hypothesis (Vonk and Povinelli 2006) stipulates that one essential difference between the cognitive capacities of humans and nonhumans is that humans, but not nonhumans, are capable of reasoning about theoretical entities that cannot take on physical form. Such entities consist of hypothetical constructs such as traits, physical forces, and mental states.

Introduction

Comparative and cognitive researchers have long debated the facets of human cognition that allow for our uniquely human abilities. Scientists quibble over the extent to which human cognition is qualitatively distinct from that of nonhumans (see Penn et al. 2008 and related commentaries), but they cannot feasibly deny that humans stand alone with regard to the capacity to alter their environments, create technology, devise symbolic systems for communication, and so on. What is more contentious is identifying the cognitive trait or suite of traits that allowed for such distinctiveness in the psychological domain.

Testing the Unobservability Hypothesis

Various claims have been made concerning cognitive feats that might be unique to humans. Candidates include imitation/culture, teaching,

deception, theory of mind (ToM), causal reasoning, language, and abstraction. Most of these cognitive processes share the requirement to represent theoreticals or constructs that cannot, in principle, take on physical form. That is, concepts for imagined but unreal entities that could be envisioned, such as Gods and other supernatural beings, do not constitute unobservables, even if such entities have never actually been observed. Vonk and Povinelli's (2006) hypothesis refers strictly to a class of constructs for things that could never be imagined in any perceptual sense. Constructs such as freedom, thought, memory, belief, sameness, and abstraction itself are constructs that exist only as theoreticals. There is evidence that humans reason about such things by virtue of the language that allows for the creation of labels and terminology for these constructs. It is far more difficult to probe for the existence of these constructs in non-human minds that do not have access to the same symbolic systems.

Therefore, one of the challenges with such a hypothesis is that it is difficult to test. Given that researchers must measure real responses to real, observable events and stimuli, and given that unobservable constructs are inferred from observables, it is very difficult, if not impossible to differentiate between cases where animals are responding to observables, and when, alternatively, they have inferred the unobservable force or entity that has given rise to the observable manifestation of such. Take, for example, the most prolifically researched hypothetical construct: ToM. ToM is the capacity to reason about the contents of another's mind (Premack and Woodruff 1978). It is not possible to know another's mental state except through either language, which is restricted to humans, or through inference from observed behaviors, postures, expressions, and other observable phenomenon. Learning to respond appropriately to another's observable indicators of their underlying mental states may come about through associative learning and by inferring potential future outcomes based on past experiences. An animal might come to recognize that another individual with bristling hair, clenched lips, stiff posture, and that is emitting threatening grunts is more likely

to attack compared to another individual with relaxed posture and a playful expression. That conclusion can be based on the observable behaviors and features alone and need not involve the inference of underlying states of anger or calm. However, any experimental test of such inferences necessarily needs to provide the observable cues that would predict the same outcome or there is nothing on which the animal could be expected to make a prediction in the first place. Thus, the existing experimental tests for presence of concepts such as mental states in other beings are necessarily confounded and unable to be diagnostic on the question (Penn & Povinelli 2007, Povinelli and Vonk 2004). The same problem exists with regards to reasoning about physical causal forces and other unobservable constructs.

One particularly promising current direction of research relies upon the notion of appearance reality distinctions and requires apes (in all of the existing tests so far) to reason about another's knowledge based on the idea that the other ape is subject to an illusion that the subject ape is privy to. Thus, the subject ape can predict that a partner will reach for a piece of food that appears to be larger, rather than a piece of food that actually is larger, if the partner is viewing the food through distorting lenses (Lurz and Krachun 2011). Lurz and Krachun (2011) have conducted several such tests, and although these tests have been met with the usual resistance from skeptics (e.g., Buckner 2015 cited in Vonk *in review*), they present a promising new direction for future research, along with the experience projection tasks first proposed by Heyes (1998), and see Povinelli and Vonk (2004) and first conducted by Vonk and Povinelli (2011). Similar to appearance/reality tests, the experience projection tests require an individual to reason about the current psychological experience of another based on previous experience in which the subject themselves experienced the same conditions. For example, subjects might be given experience with artifacts that either block visual access or allow visual access, and then are asked to predict what another individual will do when wearing these artifacts. In Vonk and Povinelli (2011), enculturated chimps were given the chance to employ a species-

specific begging gesture with experimenters wearing buckets that they themselves had previously worn. The experimenters' faces were not visible through either bucket visor, but the chimpanzees had prior experience and should have gestured to the experimenter wearing the bucket that provided visual access rather than to the experimenter wearing the bucket that had not provided visual access. In this study, the chimpanzees behaved equivocally. Karg and colleagues have conducted related studies with more mixed results (Karg et al. 2015). These types of studies remove the association between observable cues and outcomes and link observable cues only to subjective experiences that must be mapped on to other individuals, and thus may circumvent some of the criticisms of other types of paradigms.

However, a remaining challenge with the unobservability hypothesis is that although the hypothesis could theoretically be *disproved* if appropriate experimental procedures were developed and provided evidence for animals possessing such concepts, the hypothesis is difficult to *prove*, because no amount of null results supports the claim that no animal anywhere has the capacity. Systematic and inclusive null results do, however, lend support to the hypothesis when evidence amassed across various hypothetical constructs and contexts leads to the same profound differences in behavior observed between humans and other species. Researchers are also forced to answer the question as to why such an ability would evolve in humans but in no other species and what function it might serve (Vonk in review). Scientists have remained relatively mute on this last point, but it is likely that the capacity is linked to our ability for language and other symbolic systems, which allowed for an extensive communication system unmatched in the animal kingdom.

Conclusion

The extent to which nonhumans represent concepts for unobservables remains uncertain as researchers struggle to make progress with experimental paradigms that will allow for a careful

dissection of processes linked to observable features and those that depend upon an internal representation of an overarching conceptual category subsuming such features (Vonk and Povinelli 2006). However, the idea that humans and nonhumans differ in the extent to which they represent concepts of unobservables remains viable.

Definition

Unokais and Headmen are high status members of the Yanomamö tribe, located in the Amazon Basin.

Introduction

Residing within the Amazon Basin is a large tribe of indigenous peoples referred to as the Yanomamö (Sponsel 1998). These primitive people of Brazil and Venezuela were a primary focus of research by anthropologist Napoleon Chagnon (1979; Sponsel 1998). Across 35 years and approximately 25 fieldwork trips to visit the Yanomamö tribe, Chagnon documented much of the social and cultural structure of the group and came to refer to them as, *the fierce people* (Chagnon 2013). This title was chosen to depict the violent and aggressive lifestyle of the Yanomamö (Chagnon 1986a; Lizot 1985). A key illustration of the reverence with which violent behavior is held is the high status that is granted to any member of the group who has killed someone. These individuals are referred to as “unokai” and have among the highest status within the group. Acquiring social status is essential for success within the Yanomamö, particularly for male members, as it translates directly to their mating success. Political leaders within the group (i.e., headman) are also endowed with high social status. This entry will describe the Yanomamö and how status is achieved through violence, success in warfare, and political power, as well as the advantages accrued to those of high status.

Noble Savages

Napoleon Chagnon's first encounter with the Yanomamö tribe was in 1964 when the tribe was not well known and many of its villages had little-to-no contact with the outside world (Chagnon 2013). Chagnon reported that the Yanomamö people were vastly different than his expectations. He had anticipated relatively simple and nonthreatening tribal people. His expectations were to meet the delightful and peaceful humans within their natural state much like what Jean-Jacques Rousseau described in his work, *The Social Contract* (1762/1968). Instead, Chagnon found a tribe of people quite accustomed to violent acts. Early documentation of the Yanomamö describes the tribal people partaking in disturbing and violent

activities including demonstrations of physical aggression, violent raids, and killings. On the basis of his extensive work with the Yanomamö, it was evident to Chagnon that the preconceived notion that humans are innately cooperative and gentle ignores an underlying propensity for violence.

Social Hierarchy

Throughout Chagnon's work with the Yanomamö, a critical observation was the immense inequality that exists among its people. The hierarchy among men in particular has important consequences, as it is a key determinant of mating success, with men at the top of the hierarchy gaining the most mating opportunities. Two positions of high status within the Yanomamö are that of unokai and headman.

The Yanomamö, which make up approximately 25,000 people across roughly 250 villages, operate as a hierarchical society in which females reside at the bottom of the hierarchy and men move up based on status that can be obtained through acts of aggression. A headman who is in charge of the village's politics leads each tribal village and sits at the top of the hierarchy. Chagnon (2013) mentions in his writings that each headman is different in their leadership style. Some are relatively docile in their leadership tactics, while others are belligerent and violent. Individuals are placed into the position of headman according to their lineage; those who have the largest number of kin in the tribe are placed into this position of power. Although this position is typically granted through familial ties, it is also achievable with increased numbers of kin or offspring.

Other highly recognized figures within Yanomamö communities are the unokai, translated as "killed men in war." These high status men have killed another individual in battle or were involved in a severe conflict that led to killing. Like the headmen, unokai are also documented to have a greater number of sexual partners or wives and a subsequently increased number of offspring (Chagnon 1992). These high status positions are

linked to greater opportunity for sexual access to females as they illustrate to their own village honorable actions of force and intensity during warfare. Additionally, anthropological research suggests that much of the violence between tribal villages is the result of competition over resources (Sponsel 1998). The promise of such rewards incentivizes participation in warfare, as one's access to resources can improve one's ability to attract mates. Thus, these individuals are highly regarded in their culture as they take the greatest risks, which serve the function of helping to foster the success and safety of one's group.

Pursuing Status and Mates

A significant benefit for Yanomamö men with high status positions results from their participation in arranged marriages. This marriage system functions as a form of trade among families. For giving a wife, a daughter's family receives some form of payment from the receiving husband. Families look for men with prominent family lineages and men of high status to exchange their daughters with. Yanomami headman and unokai are most highly sought after for marriage. As such, men who are in positions of political power or high-achieved status have the best chance of obtaining a desirable female partner (Chagnon 1988).

In addition to arranged marriage practices, the Yanomamö also practice polygyny, allowing males to have more than one wife. This elevates the level of competition among men and incentivizes the abduction of women across villages. The competition is exacerbated by the fact that there are more males than females in the population, a fact that may be explained by the practice of female infanticide (Chagnon et al. 1979; Owl 1976). Men of high status may monopolize a large share of local females, leaving other men with few mating opportunities. This amplifies competition among men for access to the status and resources that will make them appealing to females. Only those men who are successful stand to pass on their genes to the next generation, and so selection favors aggressive and violent competition in the pursuit of enhancing one's mating

prospects. Actions that are aggressive in nature elevate a man's place in the tribal hierarchy. As one moves up in their position within the tribe, men have access to greater resources, including women.

Conflicts that take place among the Yanomamö range from minor "feats of strength" competitions, such as chest pounding competitions, to extremely violent raids of other villages. Each conflict provides males with the opportunity to illustrate their dominance, and importantly, advance their mating prospects (Chagnon 1988). Within villages, the chest-pounding or club-fighting duels are competitions of will, where males take turns beating one-another until one-person surrenders (Chagnon 1992). The men typically use their open-palms or fists, but occasionally use weaponry such as clubs or axes. Overall, these competitions function to settle disputes between men. However, if death or great injury is the result of these chest duels, divisions within villages can form, leading to the creation of a new enemy village. Ultimately, the males who endure these conflicts receive accolades for their dominance, as they are able to illustrate their strength and usefulness to the group.

When violence escalates to intergroup warfare, men who participate and who are successful in killing members of the rival village are bestowed the great honor of being named a unokai. This is because the killings contribute to a village's reputation for strength. This reputation is important because a group perceived as cowardly or weak will often be attacked. Unokais receive high status within the group and access to more mating opportunities. This incentivizes participation in continued violent and deadly intergroup competition in order to ensure one's place atop the social ladder.

Conclusion

The Yanomamö culture illustrates a tight connection between male status and mating success. Headmen are granted status by virtue of their family and descendants, whereas others engage in extreme violence to fight for their elevated status. In this volatile and conflict prone region,

aggressive behavior is the currency with which men are able to secure reproductive resources. Particularly, in this polygynous society, competition for status and subsequent mating success leads to extreme forms of violence within and across groups.

Upper Body Strength

Aaron Sell
Griffith University, Mount Gravatt, QLD,
Australia

Definition

Upper body strength refers to the muscular power of the arms, hands, and chest.

Introduction

The muscular-skeletal system evolved primarily to exert physical force onto the world, as directed by the nervous system. Such a system is – unsurprisingly – used for diverse effects in different species, e.g., mammals use it to expand and compress their lungs for respiratory purposes; virtually all animals use it for movement and to direct the senses. This entry discusses one part of this system in humans: upper body musculature and what its significance has been for human ancestors. In particular, upper body strength has been shown to be an important predictor of fighting ability and thus an aspect of mate value and a correlate of status.

When human ancestors began using bipedal locomotion more regularly, this freed the hands, chest, and arms to specialize in other kinds of muscular movement. Humans are not unique in this. Other bipedal species have evolved shrunken chests which lower their center of gravity and aids in balance (e.g., T-Rex). Other species such as (male) kangaroos have evolved more robust strength in the upper body. Humans are one such species.

For what purpose is this strength used? The answer – of course – is a list rather than an item. The upper body is used to carry altricial infants, fashion and wield tools, process and consume food, climb trees as many primates continue to do, groom, remove parasites, attend to injuries, craft shelters, and so on. Additionally, there are reasons to think that humans used upper body strength in aggression.

How Important Is Upper Body Strength to Aggression?

Technological progress in the modern world has expanded the types of aggression available to humans, e.g., explosives, ballistic missiles, firearms, Tasers, and pepper spray. While human ancestors had fewer options, they did make use of human ingenuity to supplement simple hand-held weaponry. For example, hunter-gatherers have been known to use pathogens (e.g., the Dani laced their arrows with rotting flesh), poisons, and other creative means of rendering

enemies functionless. However, an analysis of ancestral weapons has shown that all muscular-powered weapons used by hominid ancestors were powered by the upper body in particular, e.g., spears, bows, handaxes, clubs, and atlatls (Brues 1959). Additionally, unarmed combat is also heavily reliant on the upper body for punching (Carrier and Morgan 2015), choking, grasping, rending, and gouging.

This means that if human ancestors were fighting, they were doing it largely with their upper bodies. In addition, upper body strength is the most sexually dimorphic kind of strength, with human males having approximately 90 % greater upper body strength than human females, while only having 50 % greater lower body strength (see Lassek and Gaulin 2009). This means that ancestrally, males with weaker upper bodies were reliably killed or rejected by females with such frequency that they were selected out of the gene pool, leaving only the males whose developmental systems magnified their upper body strength in response to testosterone. This selective regime was presumably in place because males are the most aggressive sex and therefore pay a large price for not being able to aggress well.

Thus, upper body strength is greater in the sex that evolved to be skilful at aggression. This suggests that human males' formidable upper bodies evolved – to a large extent – for aggression. Such aggression, however, is not always deployed against other humans. Males are also the sex that engages in the most hunting, particularly big game hunting that would require great upper body strength to kill the target and to transport the meat back to family members and friends (Brown 1991). Is there evidence that upper body strength is particularly relevant to conspecific aggression rather than just hunting?

The answer is “yes.” Evidence from male assessment mechanisms (see ► [“Male Adaptations to Assess Fighting Ability”](#)) shows that such mechanisms are particularly well designed to respond to cues of upper body strength. In other words, a man who has strong legs will not appear as formidable as a man who has strong arms. Even when judging a man's fighting ability from his face or voice, judges return with estimates that

more closely track upper rather than lower body strength. In other words, men with greater upper bodies also have “tougher” looking faces and more formidable sounding voices. This connection cannot be directly causal, e.g., humans do not produce voices with their upper body musculature nor do they lift with their faces, but it does suggest that adaptations that are designed to estimate fighting ability are especially tuned to cues of upper body strength.

What Are the Correlates of Greater Upper Body Strength in Men?

Individual men with greater upper body strength are perceived as – and indeed would have been – better fighters. This has profound implications for human social relationships, because fighting ability is a relevant variable to many kinds of social interactions, specifically any relationships that involve potential aggression either in offense or defense. Not surprisingly, upper body strength in men has been shown to predict many important characteristics.

Research demonstrates that males with more upper body strength feel entitled to better outcomes, set lower thresholds for anger, and are more likely to be involved in aggression (Muñoz-Reyes et al. 2012; Sell et al. 2009, 2016). This has been interpreted in classic game theoretic terms, e.g., animals evolved to calibrate their aspiration levels to their fighting ability (“resource holding power” in evolutionary biological parlance).

Similarly, men with greater upper body strength have been shown to be more attractive to women (Fink et al. 2007) and report more sexual relationships (Sell et al. 2009, 2016; Sneade and Furnham 2016). This has been interpreted as evidence that female mate choice mechanisms are calibrated to seek more dominant males as mates, because they will sire more healthy offspring and be better able to support the female and her children or both. There is evidence of special design for this preference, for example, females who are more fearful of being attacked demonstrate a higher preference for physically formidable males (Ryder et al. 2016).

Conclusion

In conclusion, upper body strength is the kind of strength that is most relevant to ancestral combat. This is presumably why men have much more upper body strength than woman, and why human perceptual systems that estimate fighting ability focus on cues of upper body strength. Men with more upper body strength can leverage it into better treatment, and thus feel more entitlement, set lower thresholds for anger, and are more likely to deploy aggression. Such males are also more attractive to females.

Upper Body Strength and Fighting Ability

David Johnson

Michigan State University, East Lansing, MI, USA

Synonyms

Formidability assessment

Definition

Upper body strength is the most reliable indicator of fighting ability in humans.

Introduction

Assessing fighting ability was vital to humans for both natural and sexual selection. Men that could reliably assess fighting ability would have been better equipped to judiciously choose what physical conflicts to enter into, what conflicts to avoid, and when to withdraw. Women too would have benefited from assessing fighting ability accurately by choosing mates with a higher likelihood of successfully protecting them and their offspring. When considering these selection pressures across the scale of evolutionary history, it is quite likely that assessments of fighting ability would have been selected to be accurate and robust.

The best indicator of fighting ability in humans is upper body strength (Sell et al. 2012), which is

fundamentally tied to the musculature of the upper body. Individuals with greater upper body strength were better able to strike, injure, and disable competitors. Accordingly, humans should be able to assess visual cues to muscle mass in an accurate and robust fashion, and those cues should also predict success in conflict. Several lines of work have demonstrated converging support for these ideas.

Empirical Evidence

In terms of accuracy, Sell and colleagues (2009a) demonstrated that judgments of both men's upper body strength and fighting ability from photos correlated strongly with strength as measured by weight lifting equipment. These judgments were accurate at the individual level. Furthermore, strength judgments were almost perfectly correlated with judgments of fighting ability, suggesting that the cognitive program that measures fighting ability is closely tied to strength assessment. More importantly, measured upper body strength also predicted men's self-reported history of fighting and success in conflict (Sell et al. 2009b). However, a major limitation of this work is its reliance on retrospective self-report, which may not accurately reflect real world outcomes. Furthermore, these methods do not directly test what the program was designed to do: to reliably assess the victor of an actual physical fight.

However, there is some direct evidence that addresses whether the program can reliably assess the victor of a fight. This work comes from research on physical fights from mixed martial arts (MMA) competitions. Little et al. (2015) showed untrained individuals facial photographs of MMA fighters who had previously fought against each other. Despite the fact that MMA fighters are an extremely homogenous group (they are all extremely strong and are grouped by weight class), raters were able to guess who won at rates greater than chance (55 %). In addition, these judgments of fighting ability were also strongly correlated with strength judgments, suggesting that strength information was used to decide who would win.

In terms of the robustness of these judgments, there is good reason to believe that the assessment system is quick and sensitive to subtle cues. First, humans make highly accurate assessments of strength and fighting ability in seconds from merely looking at photographs of individuals. These judgments are accurate even when only facial photos are used, which obscure information about the musculature in the upper body. Similarly, humans also accurately assess upper body strength from the voice (Sell et al. 2010), and these assessments provide incremental validity above and beyond what information is gained from visual cues.

Conclusion

In sum, there is strong evidence that the assessment of fighting ability in humans is not only accurate but is also robust. Humans can accurately predict the winners of fights even when competitors are physically similar, and those decisions closely follow judgments of physical strength. Furthermore, accurate judgments of strength and fighting ability can be made even under impoverished circumstances, such as when the body is partially obscured or only voice information is available.

Definition

Humans can reliably assess upper body strength from photographs.

Introduction

Upper body strength is the most reliable cue to fighting ability in humans (Sell et al. 2009). This is at least partially because for most of human history, the most effective fighting tactics involved using the upper body to strike and injure competitors. Given that upper body strength is almost completely determined by the size of the muscles in the upper body (Lassek and Gaulin 2009), upper body musculature is a particularly salient visual cue to an individual's fighting ability. As such, the visual system is well designed to acquire those cues to body size and pass them along to the cognitive program that judges fighting ability.

Empirical Evidence

To test the accuracy of upper body strength assessments, researchers have extensively relied on photographic stimuli. The basic reasoning is that if cues to upper body strength are assessed visually, then humans should be able to accurately assess upper body strength from pictures alone. Sell and colleagues (2009) demonstrated that for men involved in strength training, judgments of upper body strength from full body photographs correlated strongly ($r = .71$) with strength as measured by weight lifting equipment (e.g., arm curl, chest press). These ratings were stable both in aggregate and at the individual level.

In order to isolate what specific cues individuals are tracking when looking at photos, Sell and colleagues (2010) also examined whether humans could accurately assess upper body strength from cues in the face or upper body alone. They also used pictures of individuals who did not engage in strength training, to test the generalizability of these programs. The results definitively showed that raters could accurately assess strength from pictures of the upper body (excluding the face) in both men ($r = .57$) and women ($r = .51$). These cues appear in face as well; raters could accurately assess strength from pictures of the face alone, although the correlations were generally weaker for both men ($r = .39$) and women ($r = .21$).

Furthermore, judgments of strength appear to genuinely track upper body strength, rather than some related cue. For example, when controlling for body size (i.e., height and weight), judgments of men's strength are uniquely predicted by actual upper body strength. Conversely, when controlling for actual upper body strength, measurements of men's height and weight have much smaller and less consistent relationships to judgments of strength. Similarly, judgments of strength from the face (which obscures information about lower and upper body strength) exclusively track upper body strength rather than lower body strength. Thus, there is compelling evidence that humans can track upper body strength and that strength assessment is not a byproduct of a system that tracks some related cue.

Finally, there is evidence that visual cues that indicate upper body strength in humans are species typical. Sell and colleagues found that American raters could accurately judge strength from facial photographs and recordings of voice for American men, Tsimane men from Bolivia, and Andean men from Argentina. These results strongly suggest that strength assessment is an evolved mechanism and not based on culturally transmitted information.

Conclusion

Upper body strength is the single best indicator of fighting ability in humans. Given the importance of accurately assessing the fighting ability of other competitors, humans developed adaptations to reliably assess upper body strength. These adaptations track upper body strength and not some other related cue (e.g., height). The adaptations are also robust, as humans can accurately assess upper body strength from still photographs. Similarly, judgments of upper body strength do not appear to be based on cultural transmission, as Americans can reliably assess the strength of men from other cultural groups.

Definition

Female membership in gangs provides women with opportunities for affiliation, protection, respect, and mate selection. Women's aggressive behavior within the gang is generally more indirect and less deadly than that of male gang members, typically directed at other females, and used as a means of mate guarding or derogation of one's rivals.

Introduction

Early research on urban gang activity focused primarily on male gang members, only mentioning female members to discuss their appearance or deficiencies as viewed by the male gang members. However, during the 1980s, there was a greater emphasis placed on the motivations underlying women's involvement in gangs. This research suggests that women join gangs for affiliation, protection, respect, and the prospect of finding a mate (Campbell 1991; Molitor 1996). Additionally, a primary focus has been placed on investigating the factors that predict females' engagement in violent behavior within the context of gangs. The research suggests that female-perpetrated gang violence is the result of mate guarding, intrasexual jealousy, defense of one's honor, or pressure exerted by male members (Campbell 1991, 1984). This entry provides an overview of research on female gang members and places the findings in an evolutionary context to help explain women's membership, roles, and aggressive behavior within gangs.

Female Gang Members

There are about 400 gangs in New York City alone with 8000 to 40,000 members in total. Of those members, it is estimated that 10% are female, although some estimate that female members account for as high as 30% of members (Laidler and Hunt 2001). The women who are members of these gangs range in age from 14 to 30. Many are married – often to male gang members – and have children (Campbell 1991). Many

of these women and girls have a lack of education and come from dangerous neighborhoods. Many also have or had an unstable, violent family life, most of which included divorces, remarriages, or girls whose parents were never married. These female gang members were usually members of a gang with both female and male members or in an all-female gang named after the male gang with which they are associated, such as “The Sandman” and “The Sandman Ladies.” There are very few all-female gangs that are not associated with an all-male gang. Before 1980, the female members of gangs were often viewed as playing unimportant or minor roles; however, more recently, their roles within gangs have been more clearly elucidated (Molitor 1996).

Women's Membership and Roles Within Gangs

From an evolutionary perspective, women's membership in gangs can be traced, distally, to mating motivations. Fundamental features of men and women's reproductive physiology have differentially shaped men and women's mating strategies (Trivers 1972). Owing to females' large obligatory investment in offspring (e.g., 9 months of gestation and a long period of breast feeding), lifetime reproductive potential is substantially limited, particularly in comparison to the reproductive capacity of men, who are limited only in their ability to gain access to mating opportunities. As a result, females best optimize their reproductive fitness by selecting high-quality mates, that is, mates who are both willing and able to invest resources into their shared offspring. Indeed, research has shown that women show a strong preference for men of high status who have high income or earning potential (Buss 1989; Buss and Schmitt 1993). In urban environments, women from impoverished backgrounds seeking high-status mates may be drawn to gangs as a means of gaining access to mates who have the ability to acquire high status and access to resources (even if obtained illegally). Partnering with such men may also offer women protection from violence (Snyder et al. 2011).

Descriptive research on women's involvement in gangs is consistent with the idea that it is women of low socioeconomic status who are drawn to gangs. Female gang members are more likely to grow up in poverty and to have been raised in a single-parent home where the mother is the primary caregiver for the family, and the father is absent (Laidler and Hunt 2001). Additionally, many female gang members have backgrounds of physical or sexual abuse (Molidor 1996).

Research is also consistent with the idea that primary motivations for gang membership include the protection, resources, and mating opportunities it provides. Indeed, the "roles" that women play in gangs are often based on their relationships to the male gang members. Research has categorized female gang members as belonging either to the "Good Girls" or "Bad Girls" group. "Good Girls" have brighter prospects for their future. Although they are likely to engage in substance use with the gang, they do so with greater restraint (Campbell 1991; Laidler and Hunt 2001). The "Good Girls" category is further divided into "Independent Women" and "Good Wives." "Independent Women" are members whose membership is temporary, as most hope to attend college and become financially independent. The "Good Wives" also have aspirations to leave the gang; however, they display a strong financial dependence on their boyfriends/husbands within the gang, making it difficult to leave (Campbell 1991).

On the other hand, the female members who fall into the "Bad Girls" group view their membership as long term, often because their options are limited. They tend to have poor money management, do not do well in school, and are at high risk for prostitution and drug addiction (Campbell 1991). Similar to "Good Girls," "Bad Girls" are also divided into two smaller groups: the "Sex Objects" and the "Tomboys." The "Tomboys" generally join in on fights with other gangs and participate in illegal activities, which is atypical in comparison to most female gang members. The male members do not appreciate the willingness of the "Tomboys" to fight, and most male members only accept them through sex, as the

"Tomboys" are generally promiscuous with the male members. However, the women in this group are also able to maintain strong friendships with other female gang members (Campbell 1991), which contrasts sharply with the female relationships of the "Sex Objects."

The women in the "Sex Objects" category are often sexually active with one or more male members of the gang. Sex provides the primary means of their acceptance by the men as most do not have friendships with male gang members outside of sex. Other female gang members distance themselves from these women through othering, gossiping, and judgment of their behavior (Laidler and Hunt 2001). Promiscuous behavior may represent a threat to the other women's ability to secure long-term investment from their male partners. When sex is freely available, there are few incentives for men to invest in long-term relationships. Women's indirect aggression may therefore function as a means of combatting the ease with which men can gain access to short-term mating opportunities (Vaillancourt 2013). Indeed, there are strong norms among female members for ensuring that women dress and act like a respectable woman. Failure to do so results in a loss of esteem by their peers. Being "respectable" includes standing up for themselves, being independent, not engaging in casual sex often, and not letting themselves lose control when under the influence of drugs or alcohol. Female members are typically more judgmental about the respectability of other female members than are the male members and will even engage in fights to defend their respectability or honor (Laidler and Hunt 2001).

Overall, women's relationships with other female members are often exceptionally different than their relationships with the male members. Female relationships are often flimsy and short-lived. Female members in relationships are often very jealous of other women as they typically depend on their partner for financial support. Many female friendships end as a result of disputes over men (Benenson et al. 2013; Campbell 1991). Women's relationships with men may be more long-lasting, though not without their own problems. Although the male members are

protective of the female members (Laidler and Hunt 2001), the women are often physically and sexually abused by them. If a woman is impregnated by a male member, that member often abandons her (Arnocky et al. 2014; Campbell 1991, 2002).

Induction of Female Members

There are many different methods of inducing new female members, depending on the gang. Some women are required to sleep with any gang member who wishes to have sex with her, often to prove that she is heterosexual. A similar type of induction includes the potential female member being coerced into sex with multiple members at a time. Other women are expected to fight many current female members at a time. These potential members are not expected to win these fights, but to prove that they can hold their own in a fight. Other women have to fight one current member of the gang, usually one of the most accomplished fighters. Another way that these women are inducted is by “walking the line,” in which the inductee walks along a line of members who beat her severely. Other times, the potential members are expected to participate in a shooting or a robbery in order to implicate them in the crime and to prove their loyalty to the gang (Campbell 1991; Molitor 1996). These induction methods are similar to hazing practices observed in other groups and which serve the function of fostering loyalty to the group (Aronson and Mills 1959).

There are, however, less violent methods of induction, including women having been associated with the gang from young ages until they are established as gang members, marrying a current gang member, or even being allowed into the gang without any kind of induction or initiation (Campbell 1991; Molitor 1996). It is also possible for gang members to leave the gang. There are two main ways to do so: actively or passively. Most members who actively leave the gang leave due to injuries obtained during a gang-related fight. Members who choose to leave the gang passively often do so by getting married or having children (Campbell 1991).

Violence and Aggression

From an evolutionary perspective, women are expected to engage in less violent aggression than men (Archer 2006; Campbell 1999, 2013). This is due to the large investment that women make in their offspring. Indeed, women are essential to the survival of their offspring in a way that men are not (Sear and Mace 2008). Additionally, there are fewer incentives for women to engage in violent competition. For men, competition with other men serves the function of increasing their mating opportunities, but given women’s low reproductive ceiling, such incentives are much weaker. The reduced benefits, and heightened costs, of engaging in violence for women yield a much lower rate of physical violence among women (Archer 2006). However, women are still motivated to compete with potential mating rivals as a means of protecting an existing relationship from mate poachers, or to attract a potential mate through the derogation of rivals (Arnocky et al. 2014; Benenson 2013). To achieve such ends, women are more likely to use indirect forms of aggression (Campbell 1999). This permits women to compete for the best mates without putting themselves directly in harm’s way.

Although women in gangs are involved in more violence than women who are not members of gangs, they commit fewer violent acts than their male counterparts in the gang. Additionally, much of the violence is directed toward their female competitors. The female gang members are often pressured by male members to commit violent acts (Campbell 1991, 1984). Many of these women would describe the fights as fair, since weapons are often excluded. Instead, most fights include the women using their teeth, nails, or any other body part in order to win the fight, unlike most male fights that use more deadly means of aggression, such as guns (Campbell 1991).

There are different roles that female gang members take part in when using violence. Most women who participate in fights are “Bad Girls.” For example, “Tomboys” use fighting and violence in intergang fights (Campbell 1991; Molitor 1996), while “Sex Objects” fight mostly with other women over jealousies about male

members. When women fight with females outside of their gang, they are mostly fighting with women who are not associated with any gang and the fight occurs without weapons. Another common type of fighting is called integrity fights which occur when a female gang member's honor has been called into question. These fights generally happen in public and are more likely to include weapons. However, overall, most intragang fights occur in private, do not typically have a victim, and generally conclude by both parties voluntarily walking away (Campbell 1984).

Conclusion

Though women's involvement in gangs is less common than that of men, there is now sufficient documentation of women's membership in gangs to begin to understand the underlying motivations for their involvement. Many female members coming from impoverished backgrounds join gangs in order to have access to the opportunities gangs provide for finding a mate who can offer protection and financial security. Women's roles within the gang are often centered around their relationships with the male members. Their dependence on the male members engenders greater competition between female members who seek to protect their partnership from female rivals, thereby leading women to participate in both direct and indirect aggression to derogate rivals of their current or prospective mates. Females tend to use such tactics to find a long-term, financially-stable mate able to support herself and her children (Arnocky et al. 2014; Benenson 2013; Buss 1989; Buss and Schmitt 1993; Campbell 1999, 2013).

Definition

Engaging in healthy and serious mental activities can help prevent the loss of cells and cell production (Shors et al. 2012).

Introduction

In recent years, one subject has become a main topic of conversation among cognitive

psychologists: the use-it-or-lose-it theory. This theory suggests that if we do not use a certain function or skill, their loss can be irretrievable or irreversible. It is well-known that cognitive decline naturally occurs after reaching a certain age. In particular, Wilson et al. (2003) have shown that the rate of cognitive decline sharply increases in the last 43 months before death. Potential contributors to cognitive decline may include a reduction of hormonal or trophic support, specific toxin exposure, or activation of the innate immune system by pathogens (Wilson et al. 2003). According to Lustig et al. (2009), a main method of testing the use-it-or-lose-it theory is strategy training. Strategy training usually involves identifying tasks older adults perform poorly on and training them on strategies that may help increase their ability to perform these tasks. Lustig et al.'s earlier work discussed different approaches to testing the use-it-or-lose-it method. Approaches used to test this method include multi-model interventions, strategy training, process-based training, and cardiovascular exercise. The current review expands upon this earlier work, describing several recent findings: some supporting the role of enrichment on buffering cognitive decline and others suggesting small or nonsignificant effects of enriched environments on cognitive decline.

Enriched Environments Can Reduce Cognitive Decline

One way the use-it-or-lose-it theory has been tested is through cognitive performance. Researchers vary in the testing techniques and variables they include in these experiments. In one example, Stine-Morrow et al. (2008) examined two groups of participants: a control group and an experimental group. Participants in the experimental group were given a test for their baseline cognitive performance and then given weekly tasks to train their cognitive function. Once a week, participants would meet at the local community center and have to work together to solve tasks that included processing speed, working memory, inductive reasoning, visual-spatial processing, and divergent thinking. This process continued for 7–8 months,

changing only following breaks in the schedule (e.g., holidays, weather). Their study focused on the effects of an engaged lifestyle on cognitive vitality, with a primary emphasis on fluid ability: the overall composite of variables including inductive reasoning, divergent thinking, and speed. They found a small, but reliable effect in the experimental group after the cognitive intervention training, relative to the control group, who did not participate in the training. However, the researchers noted that, while these group differences were reliable, they were largely limited to the training itself, without a sizable transfer to other task performance or ability. These limitations in transfer are well-documented within the working memory training literature and are not limited to studies with elderly populations (see e.g., Shipstead et al. 2012).

Other researchers have replicated these training benefits. In one recent example, McLaughlin et al. (2018) tested 14 healthy, middle-aged adults, comparing a group of adults completing brain training to another group completing trivia questions. Data were collected over a number of weeks, with participants measured on a variety of cognitive performance variables, ranging from attention to working memory, including speeded components, as well. After six weeks, the authors found significant differences across their two groups, with those in the brain training group seeing improvements in executive function, coupled with decreases in depressive symptoms. These results align with benefits associated with consistent, neurocognitive training.

Similar improvements following cognitive training were reported by Al-Thaqib et al.'s (2018) study, using Lumos Labs' Lumosity brain training as a cognitive training tool. The control group and experimental group were both assessed using the Cambridge Neuropsychological Test Automated Battery (CANTAB) before and after the experiment. Lumosity training – 15 min per day, every day, for 3 weeks – improved cognitive functions including attention and motor speed, compared with healthy control participants. These results largely mimic those described by McLaughlin et al. (2018), with their participants' improvements in executive function. Similar improvements following Lumosity training have

been documented by Mayas et al. (2014). In their study, older adults completing 20-hour-long sessions of Lumosity training showed improvements in alertness and distractibility, relative to a comparable group of older adults who did not participate in Lumosity training. Importantly, the skills they gained through these training exercises also transferred to a novel, oddball task, which differed from the tasks they had completed through Lumosity. These findings, unlike those described by Stine-Morrow et al. (2008), do suggest some amount of skill transfer following brain training.

Researchers have also examined the impact of other, individual differences, variables. One variable of interest is that of gender. In one example, Tun and Lachman (2010) showed that men and women were differentially affected by computer use, with men benefitting more from regular computer use than were women. Together, these studies illustrate some positive outcomes of training programs, with documented advantages observed beyond those of normal, healthy control participants.

Enriched Environments May Not Affect Cognitive Decline

Other findings suggest small or nonsignificant effects of enriched environments. In one example, Shute et al. (2014) had participants play either the Portal 2 video game or engage in Lumosity training. Participants in both conditions completed pretest and posttest measures involving problem-solving, spatial skills, and persistence. Portal 2 participants showed significant increases in all three measurements, relative to Lumosity participants. While Shute et al. did not conduct their experiment with older adults, they, in fact, tested a typical convenience sample of college students. Their results do highlight an important point: Cognitive function is inherently malleable, throughout an adult's lifespan, and these improvements can come from a variety of sources (including those not classically deemed "training interventions"). The authors cite repeated challenges and failures, during gameplay, as an important mechanism underlying their findings.

Meanwhile, Salthouse et al. (2003) *did* examine the effect of challenges on promoting cognitive decline in elderly populations. Their participants, ranging from 20 to 91 years of age, documented weekly activities – rating the cognitive demands of each one – and completed a number of standardized cognitive tests (pertaining to e.g., spatial ability, reasoning, episodic memory, vocabulary). Overall, the authors found little evidence to support mediation *or* moderation of age-related declines following cognitively demanding activities (e.g., preparing tax forms, reading the newspaper). Despite these findings, the authors do recommend that the elderly continue to engage in these activities, despite the potential for weak or nonsignificant effects, simply for enjoyment. Truly, there is no evidence to suggest any harm coming from these activities.

Finally, a review by Salthouse (2006) suggests there may be positive correlations between cognitive training and increases in cognitive function, though there is simply not enough “evidence” to support these claims. Again, despite the lack of evidence supporting training-related decreases in cognitive decline, those who enjoy participating in these activities and games should continue them. The joy from these activities may contribute to a higher quality of life.

Conclusion

Researchers investigating the use-it-or-lose-it theory have published some mixed results. In some cases, researchers find cognitive training activities *may* help slow the process of cognitive decline. However, in other studies there is too little evidence supporting any substantial benefit for elderly participants or that cognitive benefits may arise from other activities not pertaining to cognitive training. Despite these mixed results, researchers are in agreement that these interventions can help elderly populations in important ways, as is the case with the social- and community-based interventions. Whether these interventions translate to some significant cognitive benefit(s) in particular remains unknown. To summarize, further research is needed to find some conclusive answers as to whether training

approaches can help reduce cognitive decline in elderly populations.

Use of Mate Retention Strategies

Graham Albert¹ and Steven Arnocky²

¹Nipissing University, North Bay, Canada

²Department of Psychology, Faculty of Arts and Sciences, Nipissing University, North Bay, ON, Canada

Synonyms

Mate guarding; Mate retention

Definition

Mate retention refers to effort aimed at maintaining access to a mate.

Introduction

Mate retention tactics comprise a broad menu of behaviors ranging from acts of kindness and resource provisioning, to vigilance, manipulation, and violence. Mate retention effort often occurs in response to a perceived or actual relationship threat. Sex differences and individual differences exist in the use of specific mate retention tactics, which share the common goal of reducing the probability of partner defection or infidelity. In order to understand the origins of these behaviors, it is necessary to understand the processes that underlie mate selection and the negative implications of partner loss.

Introduction

Trivers (1972) defined parental investment as “any investment by the parent that enhances the offspring’s chances of survival at the cost of the parents’ ability to invest in other offspring” (p. 139). Most often, females invest more in their offspring than do males (Trivers 1972). Males’ amount of obligatory investment to produce offspring (i.e., copulation) is minimal (in terms of energetically “cheap” sperm) relative to the amount of obligatory investment of females, which entails energetically “expensive” gametic production, gestation, lactation, and requisite care after birth (Trivers 1972). Accordingly, females’ reproductive rate is limited compared to males’ reproductive rate, given the number of offspring that a female can produce is limited by the length of gestation; males’ reproductive rate is only limited by the number of fertile females that they can copulate with. In species where females have the greater obligatory parental investment, they are the choosier sex during mate selection (Trivers 1972). In species where males have minimal obligatory parental investment and higher yet more variable reproductive potentials, they compete with one another for access to fertile females (Trivers 1972).

Although females are often the more investing sex, some species do exhibit substantive male parental investment. For example, humans are

considered to be among the less than 5 % of mammals that engage in some form of biparental care (Geary 2000). Men contribute to rearing children by providing resources and protection, educating them, and helping them to form social alliances, often within the context of forming a monogamous (or socially monogamous) pair bond with the mother (Geary 2000). Although paternal investment is not obligatory, there is evidence that when fathers invest in raising their offspring, they are increasing the probability that the child will survive to reproductive age. In pre-industrial societies, paternal investment is associated with a reduction in child mortality (Geary 2000). For example, in the Aché of Paraguay, the child mortality rate for children with fathers who take part in childcare is half the rate for children whose fathers are absent (Geary 2000). Pair bonding can also benefit men's continued sexual access to their partners. Accordingly, ancestral men who exhibited psychological and behavioral mechanisms that facilitated some degree of monogamy and biparental investment may have been more reproductively successful than those who did not, provided that the offspring they were investing in were indeed their own.

The Problem of Infidelity

Generally, infidelity is a problem because it signifies the dissolution of the relationship and the loss of the time, energy, and resources associated with attracting that mate. However, infidelity also poses different adaptive problems for men and women. For men, infidelity represents the possibility of cuckoldry, whereas for women, it signifies the potential for the man's resources to be diverted away from her and her offspring.

Paternity uncertainty. For women, fertilization is internal, guaranteeing that they are the mothers of their offspring. However, men cannot be certain that they are the fathers of their offspring; it is possible that another man could have copulated with and inseminated their mate. Cuckoldry refers to a man unwittingly investing his time and energy rearing offspring that he believes to be his own, but are in fact the offspring of

another man (Buss and Shackelford 1997; Trivers 1972). By raising a child that is not his, a man invests in offspring that do not possess his genes – investment that could instead be allocated to attracting a new mate and producing related offspring. Moreover, men can experience reputational damage when they are cuckolded which may reduce their desirability to prospective mates and further reduce their likelihood of producing offspring. Men experience more jealousy in response to a mate's sexual infidelity than an emotional infidelity, suggesting that they have developed mating strategies that function to alert them to potential cuckoldry.

Diversion of resources. For women, infidelity represents a different adaptive problem – the possibility that her mate may divert his resources away from her and her offspring toward a different woman (Trivers 1972). Losing men's parental investment results in women having to invest significantly more time and resources in order to rear their offspring, effectively reducing the amount of parental investment that each child receives (Trivers 1972). Women experience more jealousy than men in response to a mate's emotional infidelity, ostensibly because men who invest emotionally in another woman are more likely to defect or divert resources from their current relationship. Due to the substantial investment associated with attracting a mate and rearing offspring, it would follow that both men and women would have developed psychological and behavioral adaptations to prevent partner defection.

Jealousy as an adaptive emotion pertinent to mate retention. The prevalence of jealousy in both men and women suggests that infidelity was a problem that ancestral men and women experienced (Buss and Shackelford 1997). Evolutionary psychologists contend that the emotional experience of jealousy is adaptive because it signifies a threat to the relationship and it motivates behaviors geared toward preventing the mate from defecting from the relationship (Buss and Shackelford 1997). Today, male jealousy is frequently cited as a cause of their use of violence in romantic dyads. Jealousy might also relate to women's mate retention efforts. For example,

Arnocky et al. (2012) found that among heterosexual women currently in romantic relationships, jealousy predicted women's use of social aggression toward partners and peers and that physically attractive women reported being the targets of other women's social aggression most often, presumably because they constitute the greatest intrasexual threat to other women.

Why Engage in Costly Mate Retention Efforts?

In order to understand why individuals might engage in costly mate retention tactics, even in the absence of an absolute threat to the relationship, it is important to consider that human decision-making is sometimes biased, such that whenever the costs of errors from two different choices differ in their severity (in terms of reproductive fitness), individuals should be biased toward making the choice which minimizes the cost of the error (Haselton and Buss 2000). From an "error management" perspective, behaviors which might dissuade partners from defecting should be common among humans given the cost of engaging in such behaviors is often less than the cost of failing to maintain a desired pair bond (i.e., losing a reproductively valuable partner). Behaviors that are explicitly or implicitly aimed at maintaining a pair bond are commonly referred to as mate retention tactics. Mate retention tactics encompass a wide range of behaviors that individuals use to prevent partner infidelity and defection.

Taxonomy of Mate Retention Tactics

Conceptually, mate retention tactics can be divided into two broad categories: cost-inflicting behaviors and benefit-provisioning behaviors (Buss 1988). Cost-inflicting mate retention behaviors function to reduce partners' self-esteem and make them feel unworthy of the current relationship or to induce fear and social isolation, all of which might increase the probability of them remaining in the relationship. Conversely,

benefit-provisioning mate retention behaviors function to reduce the likelihood of partner defection by enhancing the partner's satisfaction with the relationship (Buss 1988). Mate retention tactics can also be categorized based on the individual to whom the behaviors are directed. Intrasexual manipulations are behaviors that are directed toward same-sex competitors and function to deter them from attempting to mate with the individual's partner. Intersexual manipulations are behaviors that are directed toward the partner which function to prevent them from straying from the current relationship.

Intrasexual manipulations. Mate retention tactics within this category include public signals of possession and intrasexual negative inducements (Buss 1988). Public signals of possession function to let same-sex competitors know that the individual they may be interested in pursuing is already in a relationship. These tactics include verbal signals of possession (e.g., introducing partner as their wife/husband or girlfriend/boyfriend), physical signals of possession (e.g., holding partner's hand in front of members of the same sex), and possessive ornamentation (e.g., giving partner jewelry to signify to others that they are in a relationship; Buss 1988). Intrasexual negative inducements involve the individual engaging in direct action toward same-sex competitors to deter them from attempting to co-opt their partner. These tactics include derogation of one's own mate to competitors (e.g., telling members of the same sex terrible things about partner so they would not be interested in them), intrasexual threats (e.g., yelling at an individual for looking at their partner), and violence (e.g., hitting someone who made a pass at their partner; Buss 1988).

Intersexual manipulations. Mate retention tactics within this category include direct mate guarding, intersexual negative inducements, and intersexual positive inducements. Acts of direct guarding involve closely monitoring the activities of a mate (Buss 1988). Within the category of direct guarding, there are several strategies including vigilance (e.g., calling a partner at unexpected times to find out what they are doing), concealment of mate (e.g., taking partner away from a social gathering where same-sex competitors are

present), and monopolization of their time (e.g., spending all of their free time with their mate; Buss 1988). Intersexual negative inducements sometimes function to lower the partner's self-esteem so that they do not feel worthy of the current relationship. Intersexual negative inducements include infidelity threat (e.g., flirting with others in front of partner), punishing a mate's infidelity threat (e.g., getting angry with partner for flirting), emotional manipulation (e.g., making the partner feel guilty about talking to members of the opposite sex), commitment manipulation (e.g., demanding a total commitment from partner), and derogation of competitors to one's partner (e.g., insulting same-sex competitors physical appearance in front of one's partner; Buss 1988). Finally, intersexual positive inducements function to increase the partner's satisfaction with the current relationship. They include resource display (e.g., giving gifts to partner), sexual inducements (e.g., giving into partners sexual requests), appearance enhancement (e.g., dressing nicely), emphasize love and caring (e.g., complimenting partner on appearance), and submission and debasement (e.g., doing whatever the partner wishes). The sexes use these tactics with different degrees of frequency and with varying degrees of effectiveness.

Men's Use of Mate Retention Tactics

Based on parental investment theory, men should use mate retention tactics that involve providing their mate with resources, because this would signify that they are able to provide for their mate and any offspring they may have with survival-enhancing resources (Buss 1988; Trivers 1972). In this manner, men are conforming some of their mate retention efforts toward fulfilling the mate preferences of women, who may themselves benefit from an expressed preference for men who are able to provide resources (Trivers 1972). Indeed, Buss (1989) found that across 37 cultures, women reported a stronger preference for resource-provisioning abilities in a mate than did men. In the Aché of Paraguay, a society of hunter-gatherers, men who are better hunters tend to have

greater reproductive success, demonstrating that women may use men's resource-provisioning ability when selecting reproductive partners (Kaplan and Hill 1985). Furthermore, women prefer to mate with men who are older than themselves because these men are more likely to be financially stable and capable of providing resources (Buss 1989). In Buss's (1988) seminal study on men's and women's use of mate retention tactics, men reported engaging in resource display, including acts of gift giving, more often than women. Men who engage in benefit-provisioning mate retention strategies sometimes give their partners gifts when they are trying to secure their commitment (Buss 1988). Men are more likely to offer gifts to their romantic partners than are women (Jonason et al. 2009). Gift giving is a strategy that some men may use when trying to prevent a mate from defecting from a relationship (Jonason et al. 2009). By providing partners with gifts, men may be enhancing their mate value because they are communicating to their partner that they are able to provide resources. Indeed, some research has shown that the probability and value of gift giving is related to indices of individuals' income (Garner and Wagner 1991).

Men who have higher mate value (indexed here by their annual income and status striving) are more likely to use benefit-provisioning mate retention behaviors than men of lower mate value, who tend to resort to using cost-inflicting mate retention strategies with greater frequency. Generally, mate retention tactics that are judged to be most effective for men fall into the category of benefit provisioning and include being kind, caring, affectionate, and complimentary, whereas tactics that are judged to be ineffective fall into the cost-inflicting category and include hitting one's partner and derogating them in front of others (Buss 1988). It is important to note that the frequency and type of mate retention tactics that men use are not static but are under the influence of environmental factors. Two such factors that influence men's mate retention behaviors are partner's attractiveness and partner's fertility.

Partner's youth and attractiveness. Although young and attractive women are highly desirable partners (Buss 1989), forming a relationship with

these women comes at a cost because they are highly sought after by other men and may be more likely to be unfaithful (Hughes and Gallup 2003). Women with lower waist-to-hip ratios (WHRs), a physical trait of women judged by men to be attractive, report cheating on their partner more frequently than do women with higher WHRs (Hughes and Gallup 2003). Moreover, women who perceive themselves to be more attractive than their partner are more likely to flirt with other men and are more resistant to their partner's mate-guarding attempts. Men may use their partner's youth and attractiveness as cues to assess the probability that they will be unfaithful. In support of this, men married to younger and more attractive women engage in more frequent use of mate retention tactics including concealing their partner, emotional manipulation, commitment manipulation, verbal signals of possession, and violence against same-sex competitors, compared to those men married to older and less attractive women (Buss and Shackelford 1997). Men mated to more attractive women also engage in more frequent in-pair copulation (IPC; i.e., they have sex with their romantic partners more often; Kaighobadi and Shackelford 2008). Kaighobadi and Shackelford (2008) suggested that men married to attractive women might copulate with them more frequently as a strategy to prevent them from being cuckolded. By frequently introducing sperm into their partner's reproductive tract, they are enhancing the probability that their partner's offspring are also their own (Goetz et al. 2005).

Partner's fertility. In humans, ovulation is largely concealed; however, there is some evidence that the frequency and intensity of men's mate retention behaviors are influenced by their partner's fertility (Gangestad et al. 2002). Women report that their partners were both more attentive and more proprietary near ovulation (i.e., in the late follicular phase of their menstrual cycle; Gangestad et al. 2002). Men engage in more expressions of love and affection and are more self-assertive when their partner is fertile (Gangestad et al. 2014; Pillsworth and Haselton 2006). The increased frequency and intensity of men's mate retention behaviors during the late follicular phase of their partner's cycles is logical

because this is when they are most susceptible to being cuckolded. In addition to being vigilant about the possibility of mate poachers (i.e., individuals who try and co-opt individuals from existing relationships), men must also be vigilant about their partners straying from the relationship. Women are most interested in engaging in extra-pair copulation (EPC) when they are fertile (Gangestad et al. 2014). This is especially true when women perceive their partner to be less attractive than themselves (Pillsworth and Haselton 2006) and may reflect a dual mating strategy whereby women try and obtain good genes from one man and resources and commitment from the other.

Women's Use of Mate Retention Tactics

Women's mate retention behaviors also align with parental investment theory (Buss 1988; Trivers 1972). Like men, women seem to conform some of their mate retention efforts toward satisfying the mate preferences of the opposite sex. For instance, men have developed a preference for cues to physical attractiveness, which may signal youth and fertility in a partner (Buss 1989; Trivers 1972). Across cultures, men consistently rate physical attractiveness as more important in a mate than do women (Buss 1989). Additionally, men tend to prefer women who are younger than themselves because these women have greater reproductive value (i.e., more childbearing years). Unsurprisingly then, women's mate retention behaviors are often focused on making themselves appear more reproductively valuable. Women, more than men, use appearance enhancement as a mate retention tactic (Buss 1988).

An alternative mate retention strategy for women involves flirting with other men in front of their partners to induce jealousy (i.e., infidelity threat). Partner's sexual infidelity is significantly more costly for men than for women as it can result in genetic cuckoldry. Women's infidelity threats may serve to make their partner experience sexual jealousy and engage in mate retention tactics to secure the relationship (Buss 1988). Mate retention tactics that are judged to be most

effective for women involve appearance enhancement (e.g., dressing nicely and wearing makeup; Buss 1988). Tactics that are judged to be least effective fall into the cost-inflicting mate retention category and include hitting one's partner and snooping through their personal belongings (Buss 1988). However, some research has shown that women may employ subtler forms of indirect or social aggression toward partners (behaviors such as "I try to make my romantic partner jealous when I am mad at him," "I give my romantic partner the silent treatment when he hurts my feelings in some way," and "I have threatened to break up with my romantic partner in order to get him to do what I wanted") and peers (behaviors such as "talked about others behind their backs," "excluded others from a group," "made other people not talk to others," and "been bitchy toward others") as a form of mate retention (Arnocky et al. 2012).

Partner's resource-provisioning ability. Women engage in more mate retention behaviors when their partners have higher incomes and have higher levels of status striving (Buss and Shackelford 1997). Specifically, women married to men with higher incomes reported engaging in more acts of vigilance (e.g., checking up on partner at unexpected times) and infidelity threat compared to women married to men with lower incomes (Buss and Shackelford 1997). Women have evolved to prefer men who are capable of providing their offspring with survival-enhancing resources (Buss 1989; Trivers 1972). Women might engage in mate retention tactics more frequently and with greater intensity when their partners are wealthy, because the cost of losing a valuable partner, who is capable of providing large amounts of resources, is significantly more detrimental than losing one who can provide meager amounts of resources.

Concurrent Mate Retention Tactics

Derogation of partner and partner violence. Concurrent mate retention tactics are tactics that are commonly used together when individuals are

trying to prevent relationship defection (Shackelford et al. 2006). Men who engage in more intersexual negative inducements (e.g., derogating partner in front of others), direct guarding (e.g., taking partner away from social gatherings where men are present), and intrasexual negative inducements (e.g., threatening same-sex individuals for looking at their partner) are also more likely to insult their partner as a mate retention tactic (McKibbin et al. 2007). Moreover, men who are more likely to use intersexual negative inducements, direct guarding, and intersexual negative inducements are also more likely to engage in acts of intimate partner violence (IPV) when they suspect that their partner has committed an infidelity (Kaighobadi et al. 2008). Furthermore, men who engage in mate retention tactics within the category of vigilance (i.e., frequently monitoring partner's activities) are more likely to commit IPV when they suspect infidelity (Kaighobadi et al. 2008). Men's use of IPV may function to (1) punish the partner, (2) discourage them from committing future infidelity, and (3) signal to same-sex competitors that they are capable of inflicting violence on others (Arnocky et al. 2015). To this end, IPV may represent the extreme of a cost-inflicting mate retention strategy that some men and women use when other mate retention tactics are unavailable to them or have failed to be effective at reducing the perceived probability of partner infidelity.

Forced in-pair copulation. Men who perceive that their partner has been unfaithful are also more likely to engage in forced in-pair copulation (FIPC; Goetz and Shackelford 2006). Men's use of FIPC and other acts of sexual coercion is related to their use of cost-inflicting mate retention tactics such as punishing mate's infidelity threat, emotional manipulation, derogation of competitors, and violence against rivals (Goetz and Shackelford 2006). When men suspect that their partner has been unfaithful, they may experience greater urgency to copulate with their partners (Goetz and Shackelford 2006). Their partner's resistance to copulating with them may signify that their partner has been unfaithful and may prompt men to engage in acts of sexual coercion including FIPC. Infidelity signals may cause men

to engage in acts of sexual coercion including FIPC as a means to introduce their own sperm into their partner's reproductive tract and/or to displace rival semen from their partner's reproductive tract (Goetz and Shackelford 2006).

Compensatory Mate Retention Tactics

Compensatory mate retention behaviors function to compensate for additional factors that increase the likelihood that a partner will commit infidelity or abscond from the dyad. Some of these factors include time spent away from the partner and the individual's mate value. As the proportion of time that a couple spends together decreases, the probability of a partner's infidelity increases (Baker and Bellis 1993). To reduce the chances of being cuckolded, men who had spent a greater proportion of time away from their partners since the couples last copulation reported (1) a stronger attraction to their partner, (2) that their partner was likely more attractive to other men, (3) a stronger interest in copulating with their partner, and (4) that their partner had an increased interest in copulating with them (Shackelford et al. 2002). Men's increased desire to copulate with their partner after a period of separation may function to introduce their sperm into their partner's reproductive tract and reduce the probability of their partner being fertilized by the sperm of a competitor.

To provide further support that men engage in compensatory mate retention behaviors after periods of partner separation, Gallup et al. (2003) found that men engage in semen-displacing behaviors (i.e., behaviors designed to displace rival's semen from their partner's reproductive tract; Gallup et al. 2003). Specifically, after periods of partner separation, men reported engaging in deeper and more vigorous penile thrusting during copulation with their partner (Gallup et al. 2003). When the penis is inserted deep into the vagina, the glands and coronal ridge may function to displace rival semen from the reproductive tract (Gallup et al. 2003).

Men's mate value also influences their tendency to engage in compensatory mate retention

tactics. Height is one characteristic that is closely associated with men's mate value. Taller men tend to be healthier and possess other cues associated with viability, such as low fluctuating asymmetry (Manning 1995). Subsequently, women report being more attracted to taller men. Shorter men in romantic relationships report greater levels of jealousy than do taller men (Brewer and Riley 2009). Furthermore, shorter men are less likely to engage in mate retention tactics that would jeopardize their current relationship than taller men are, perhaps because they are aware that since they had lower mate value, their partner would be more likely to defect from the relationship if they engaged in these behaviors (Brewer and Riley 2009). This suggests that individuals' own mate value influences the type of mate retention tactics employed.

Individual Differences in Mate Retention Tactics

Individuals who score high on the traits of the dark triad (i.e., psychopathy, Machiavellianism, and narcissism) are more likely to engage in cost-inflicting mate retention tactics, such as punishing mates' infidelity threat and violence against rivals, than are individuals who score low on dark triad traits (Jonason et al. 2010). Machiavellianism is a personality trait that is associated with distrust of others and a motivation to take advantage of others for personal gain. Individuals who score high on this personality trait tend to engage in more acts of direct mate guarding, suggesting that they are distrustful of their partners (Brewer and Abell 2015). Similarly, men who have low levels of emotional stability engage in more cost-inflicting mate retention tactics (McKibbin et al. 2014). These men may be hypersensitive to potential relationship threat. Conversely, individuals with high levels of honesty-humility are less likely to engage in mate retention tactics that involve manipulating or deceiving their romantic partners (Holden et al. 2014). Furthermore, men who score high on the agreeableness dimension of the five-factor model of personality tend to engage in more

benefit-provisioning mate retention tactics; these men also report greater interest in, and more time engaging in, oral sex with their partner (a form of sexual inducement). Women who score high on the conscientiousness dimension of the five-factor model of personality also engage in more benefit-provisioning mate retention tactics and report greater interest in, and more time spent engaging in, oral sex with their partner (Pham and Shackelford 2013).

Coalitional Mate Retention

Coalitional mate retention refers to tactics that individuals engage in to help prevent their friend's partners from defecting from the relationship (Pham et al. 2015). The tactics that individuals employ to help their friends include praise (saying positive things about their friend to his or her partner), vigilance (watching their friend's partner's behavior), therapy (repairing the relationship between the friend and his or her partner), monopolizing friend's partner's time (spending a great deal of time with the partner so they cannot spend their time with a same-sex competitor), and violence (performing acts of violence against friends' rivals; Pham et al. 2015).

When individuals engage in acts of coalitional mate retention, they may be behaving altruistically, since these behaviors do not provide them with any direct benefit. Perhaps engaging in acts of coalitional mate retention functions as a costly signal, because only mated individuals who feel as though their relationships are stable or single individuals who feel that they can easily attract a desirable partner are likely to allocate time and energy enhancing their friends' romantic relationships (e.g., Arnocky et al. 2014b). It could also be that acts of coalitional mate retention are a form of reciprocity (Boyd and Richerson 1989). Individuals who engage in acts of coalitional mate retention may expect the friends who they have aided to engage in acts of coalitional mate retention when they experience relationship threat (Boyd and Richerson 1989). Men are less likely to ask their male friends to engage in coalitional mate retention tactics which would

suggest that men commonly view same-sex friends as competitors (Pham et al. 2015). Requesting help from male friends may indicate that the partner is more willing to defect from the relationship, which may cause these male friends to engage in mate-poaching attempts (Pham et al. 2015).

Role of Emotion in Motivation of Mate Retention

The experience of anxiety may function to help men and women identify and solve adaptive problems (Buss 1990). Specifically, the experience of anxiety may promote corrective behaviors that aid in survival and reproductive success via the maintenance of social relationships (Buss 1990). The experience of social exclusion is detrimental to an individual's reproductive fitness; moreover, social exclusion is not arbitrary but motivated by the individual's interaction with group members (Buss 1990). One such group where exclusion is particularly harmful is the romantic dyad. Individuals have evolved adaptations in the form of emotional experiences to prevent infidelity and partner desertion. The emotional experience of anxiety and jealousy may function to identify relationship threat and motivate the individual to engage in behaviors to prevent or reduce the intensity of relationship threat. Individuals with high levels of anxiety may be hypersensitive to the threat of partner infidelity. Men who perceived greater risk of partner infidelity exhibit higher levels of self-reported anxiety and are more likely to engage in cost-inflicting physical, sexual, and psychological aggression toward their partners (Arnocky et al. 2015). Women with lower levels of self-perceived mate value (perceived physical attractiveness and value as a mate, relative to other women) are more likely to use cost-inflicting mate retention tactics such as flirting with other men and threatening to terminate the current relationship (Arnocky et al. 2012). These behaviors may function to lower their partner's self-perceived mate value and subsequently reduce the likelihood that their partner will defect from the relationship.

Environmental Factors That Influence Mate Retention Tactics

Operational sex ratio. Environmental factors such as proportion of viable mates available also affect the frequency and intensity with which individuals engage in mate retention behaviors (Arnocky et al. 2014a). Operational sex ratio refers to the number of fertile females in the population relative to the number of sexually active males. When men and women are primed to believe they are members of the abundant sex (i.e., they are primed to think that opposite sex individuals are scarce relative to the number of same-sex individuals in a population), they report more jealousy when imagining their partner flirting with an attractive member of the opposite sex and a greater willingness to engage in acts of intersexual negative inducements (e.g., calling the person a derogatory name or slandering them in front of others) toward that rival (Arnocky et al. 2014a). Men are also more likely to reduce their sociosexuality (indicating greater orientation toward maintaining a single partner) when they believe mates to be scarce relative to abundant (Arnocky et al. 2016).

Conclusion

Mate retention tactics function to prevent partner defection. Attracting and securing a mate often requires the individual to expend a great deal of time, energy and resources. Dissolution of a relationship signifies the loss of the time, energy, and resources associated with securing the partner. Partner infidelity is one of the foremost threats to a relationship and poses unique problems to men and women. Men's mate retention behaviors are designed to reduce the risk of cuckoldry, whereas women's mate retention behaviors are designed to prevent men from deserting them. Mate retention behaviors are not static, but vary in the type employed, the frequency, and intensity with which they are utilized, and are based on a wide range of factors such as the mate value of both the individual and their partner, partner's fertility level (in the case of women), the operational sex

ratio of the environment, and the presence of friends within the environment.

Definition

Utilitarianism is a consequentialist theory of ethics that promotes actions that tend to produce

the greatest amount of welfare or happiness and deems immoral those actions that tend to do otherwise.

Introduction

Although other philosophers have supported ethical theories with utilitarian considerations, Jeremy Bentham is considered to be the first to systematize an ethics based on utility (Shaw 1999). Bentham, and his supporters, hoped that their utilitarian approach would serve as a radical reforming of social, political, and legal institutions (1999). Other prominent proponents of utilitarian ethics include John Stuart Mill, Henry Sedgewick, and Peter Singer.

At the core of any utilitarian ethics, is principle of utility (also known as the greatest happiness principle). The greatest happiness principle posits the following: Any action that produces the greatest amount of welfare or happiness are right and those that tend to do otherwise are wrong. Historically, a number of methods have been used to put the evaluative principles of utilitarianism to work. Here, I will focus on two: (1) act-utilitarianism and (2) rule-utilitarianism.

Act- and Rule-Utilitarianism

Act-utilitarianism, as the label implies, focuses on an agent's particular actions and whether those actions produce the best consequences (1973). To bring this out, consider two varying cases of neighborliness. The first involves a neighbor who has a reputation for having a green-thumb, carrying the *good* intention of helping another neighbor with their garden. Although neighbor Greenthumb provides what she believes to be the best advice, her neighbor's garden ends up not going that well. And just to not complicate things, neighbor Greenthumb also partakes in the building and planting of the garden in addition to providing advice. Now, consider another case where neighbor Greenthumb wishes ill-will toward their neighbor and their general gardening

efforts (i.e., does not wish anyone else having a yard of juicy tomatoes and almost otherworldly beautiful rose bed), and decides to do her best to sabotage the garden in such a way where it is not quite obvious. But, despite her best efforts, the opposite ends up happening – the garden turns out to be a good one. An act-utilitarian would evaluate the actions, perhaps even begrudgingly, as having been wrong in the first case and right in the latter. This should make clear, generally, a clear distinction between consequentialism and its theoretical opposite deontology.

Now, one's response to this obviously counter-intuitive evaluative result is to appeal to an agent's adherence to a set of rules that tend to produce the best consequence or greatest amount of welfare. This is just what rule-utilitarianism attempts to do. For a rule-utilitarian, an action is judged "by the goodness and badness of the consequences of a rule that everyone should perform the action in like circumstances." Another way of putting this is that an agent's action will be deemed morally right or wrong based on its coherence to a set of rules that tend to improve welfare when followed. Going back to our example above, a rule-utilitarian would evaluate the actions of our two neighbors quite differently. In the case of the first neighbor, the rule-utilitarian would argue that although their actions did not result in the best consequences, they did adhere to generally accepted principles or rules that do tend to produce the best consequences, whereas the actions of our second neighbor will be judged as being in the wrong, given that it is inconsistent with utility-maximizing rules and principles.

There are primary reasons that proponents of utilitarianism have favored act-utilitarianism over rule-utilitarianism. First, as J.C.C. Smart posits, agents run risk of becoming rule worshippers. Rule worship can often produce bad consequences that might put into question an agent's decision to not make exception. One response to this is that these commitments should be considered akin to appealing to rules of thumb, which tend to be weaker. Thus, some exceptions are allowed. However, as agents continue to make exceptions, rule-utilitarianism will eventually dissolve into a commitment to one rule: act in such a way that our actions produce the

greatest amount of happiness. This, however, is just what act-utilitarianism demands. For these reasons, and others, act-utilitarianism is considered the more authoritative form.

The Psychology of Utilitarianism

Given the theoretical commitments of utilitarianism to well-being and welfare, it is only natural that psychology and neuroscience would have a few things to say about the practical implications of utilitarianism. One issue in the area of evaluating the merits of ethical theories concerns whether ethical theories ought to incorporate emotional inputs or whether they should be purely cognitive (derived from rational procedures). Now, both Kantian deontology and utilitarianism are theories that provide their own cognitive procedures to derive right actions. So, what question that can be asked is: which one is *more* or *actually* cognitive?

According to Joshua Greene, this debate can be better answered by the sciences by recognizing something Greene believes philosophers have failed to acknowledge: the terms "deontology and consequentialism refer to psychological natural kinds" (37, 2007). Relying on the moral dilemmas provided by Judith Jarvis Thompson (i.e., *the switch case* and *the footbridge dilemma*), Greene comes to conclude that the traditional responses to each case (to pull the switch and to not throw the person over the bridge) rely on different cognitive processes. Further, given our evolutionary development, we rely on our emotions when responding to dilemmas that require *up-close-and-personal* interactions (2007). This entails two things about the two approaches to moral decision-making. In the paradigmatic consequentialist decisions in the *switch case*, emotional response is low, whereas in the *footbridge case*, where paradigmatically deontological responses are given, emotional responses are high (2007). From these observations, Greene concludes that consequentialism is the more cognitive of the two theories. From this, given the commitment to cognitive theories, it follows that utilitarianism should be favored over no consequentialist ethical theories.

Conclusion

In this entry, I have presented utilitarianism as an ethical theory that is composed of three elements: (1) consequentialism, (2) hedonist/welfarism, and (3) impartial. The latter two commitments provide ample room for evolutionary psychologists to inform the sort of cost–benefit analysis proponents of utilitarianism favor. For example, evolutionary psychology can provide accounts of the sort of psychological natural kinds that are necessary to improving welfare. Further, it can give us an account of what sort of situations cause us to diverge from the normative demands consequentialism typically proscribes.

Introduction

Rational choice theory, the dominant theoretical paradigm in most social sciences, is a framework for understanding and often formally modeling social and economic behavior. Choice and utility are alternative normative foundational notions for rational choice theories in economics, political science, moral philosophy, and public policy. They are, to an extent, inter-derivable. If economic utility, or psychological value, is viewed as basic, then choice can be explained as aiming to maximize utility or value. If choice is viewed as basic, then a utility or value scale can be derived such that preferred options have higher utility. These derivations only hold given that certain consistency conditions, such as transitivity, hold in patterns of choice. Both choice- and utility-based normative (rational) theories of how people, governments, or societies should act come under

strain if these conditions are violated; to the extent that people's choices are not consistent, it is, after all, inevitably difficult to determine what they want.

This article discusses psychology and economics as typical examples of the rational choice approach. Rational explanation in psychology is very widespread, from rational analysis (Anderson 1990), expectancy-value theories in social and health psychology (Hewstone et al. 2007), ideal observer models, mental logics and probabilistic frameworks, evolutionary accounts, and informal "folk psychology" explanation of behavior in terms of beliefs and desires (Oaksford and Chater 2007). Other social science disciplines such as criminology, law, sociology, political science, and philosophy also use rational choice theory as their main theoretical framework (Elster 1986; Kreps 1990), and hence the arguments presented in this article apply to these disciplines too.

However, context effects in judgment and decision-making are widespread (Vlaev et al. 2011), causing inconsistent values and choices (e.g., preference reversals). Such effects violate rational norms and, therefore, undermine rational explanation of behavior. How can we accommodate striking examples of inconsistent preferences into more standard rational assumptions?

Context and Value

The central argument is evolutionary in nature. In particular, there is a fundamental problem with the conceptualization of the individual in psychology, behavioral sciences, economics, and public policy. This is the human evolved tendency to make local, contextualized inferences, which could lead to global inconsistency in behaviors across *contexts* (situations, domains, and environments). This seems to reflect an evolved, basic property of human cognition that applies right across psychology, from the basic psychophysics of sound perception right through to high-level cognitive processes in judgment and decision-making (see Vlaev et al. 2011).

The argument proposed here is that rationality assumptions typically hold *locally*, i.e., within a

context, but not globally across contexts. It is as if we have a big library in our heads, and we can only look at a few books at a time when we make up our mind on a specific issue. This view preserves the picture of humans as creatures striving to make sense of, and hold consistent beliefs about, the world and their behavior in it, which is exemplified in our need to hold noncontradictory beliefs. For example, when our behavior and our self-beliefs are in conflict, often it is our beliefs and attitudes that get adjusted – so they are consistent with our behavior (Festinger 1957).

The cognitive system may attempt to maintain local consistency, by following rational principles. If the information available to the "processor" is limited by processing resources, time constraints, motivation, and memory accessibility (Kruglanski and Gigerenzer 2011), then this process will still produce biased inferences – determined by what information is immediately available from the senses or from memory. For example, many *attribution biases* (Ross 1977) share the common tendency to overvalue dispositional (i.e., personality-based) explanations for the observed behaviors of others while undervaluing situational explanations for those behaviors. This interpretation makes sense locally unless we integrate evidence from our experiences on other similar situations, look for unseen causes and less-salient factors, ask oneself how one and/or most people would behave when put in the same situation, take into account the fact that we may unconsciously want to avoid regret and disappointment, and so on, which are all very costly and take time, and even then, it may not be properly integrated into the inference process because of attentional limitations and constraints on the amount of information we can hold in our working memory (Miller 1956). However, even though global information is hard to obtain and integrate, if people are able, or enabled, to do so, their inferences are likely to be accurate or rational (see Gilbert 2002).

Similar processes occur in other domains, such as affective forecasting, where people tend to overpredict the duration of affective reactions to future events, which is attributed to *focalism* – focusing too much on the event in question and

not enough on the consequences of other future events; but asking people to think about other future activities reduces the bias (Wilson et al. 2000). Buehler et al. (1994) found that people underestimate how long it will take them to complete future tasks – the so-called planning fallacy, which is explained by focusing too much on the future task and not enough on past experiences with similar tasks. However, bringing about unseen and unforeseen pieces of information, causes or consequences, can help people make less biased judgments in other domains such as probabilistic forecasting (Larrick 2004).

In essence, whatever information is currently or locally available determines judgments and decisions. This process can initially rely only on sampling external information. For example, Bem's (1967) *self-perception theory* proposes that we form our attitudes, opinions, and other internal states by observing our behavior and concluding what attitudes must have caused them. The theory suggests that people induce attitudes without accessing internal cognitions and moods, which is done by reasoning about one's own overt behaviors rationally in the same way a person attempts to explain others' behaviors (Robak et al. 2005). Thus, instead of endorsing "global" beliefs and attitudes about what is universally good or just for them, humans tend to engage in local, situational inferences. Naturally, after many repetitions in various contexts, such attitudes might become universally endorsed, partially due to enhanced memory traces, but this can hardly apply to most everyday occasions where attitudes are expressed in decisions and behaviors.

What is known as the *bounded rationality* paradigm (Simon 1992) also proclaims that the sophisticated calculations invoked in decision theory and economic analysis are known to be beyond the computational powers of the brain. The argument proposed here goes beyond in deriving some universal implications for most descriptive models of decision-making, which leads to the core principle that decisions are relative, in a specific way, to what is embedded in the local context. This view has implications for certain rational choice-based disciplines, such as economics where people are assumed merely to have

ordinal preferences between outcomes – they are assumed *not* to assign *cardinal* values to outcomes (Cooter and Rappoport 1984). The assumption is that people prefer fish to salad; but that they have no grip on *how much* they prefer fish to salad; they do not know, for example, whether they prefer fish to salad more or less than they prefer steak to pasta. The view proposed here implies that the practice in many areas of economics is supported, rather than undercut, by psychological results, but only as long as the context (set of alternative choice options) does not change drastically. If the context *does* change, then this preference ordering may reverse (so that salad is preferred to fish). Indeed, there is evidence that behavior is consistent *within* contexts even though it is globally unstable when behaviors across different context are considered (see Ariely et al. 2003). People seem to be able to have *locally ordinal* (stable and consistent) preferences between outcomes within a particular context. Therefore, economic theory's ordinalist assumptions are implausible only when single utility function is used to model choice behavior across different contexts, in order to create a global preference ordering.

Context and Decision-Making

If humans evolved to represent utility, or attribute values, by making local, contextualized inferences, then there should be no fixed zero point on the utility/value scale, and the utility will shift depending on the context provided by the other available options. A number of experiments have investigated the effect of the context on decision-making. For example, researchers have repeatedly found that the attributes of the previously or currently seen choice options (e.g., risky prospects) influence the decisions about a current option, which suggests that options are not considered independently (see Vlaev et al. 2011, for a review of the evidence). Note that existing models of rational choice are typically based on the underlying assumption that only the attributes of the choice option need be considered when reaching a decision.

Stewart et al. (2003) report similar demonstration of local, contextual consistency in an experiment where participants were given a set of four options as possible certainty equivalents (CE) for a series of prospects. Participants were asked to decide on a CE for the prospect and then select the option closest to their estimate. For each prospect, the CE options were either all lower in value or all higher, but choices were rank correlated across contexts: those who choose low options in one context also choose low options in the other context. Therefore, there is consistency between the choices within a particular context, i.e., people are *locally ordinal*.

These experiments are also based on an account that assumes that when people judge the attractiveness, and thus their preferences for a choice option, they do so by comparing each option with other options, instead of matching it against some stable internal scale for absolute judgment. If absolute judgments are impossible, because judging by how much one alternative is better/worse than another changes depending on the other cognitively available alternatives, then the *only* reliable judgments that individuals can make are ordinal judgments, i.e., that one option is *better* or *worse* than the other, without necessary being able to say by how much. This is because such judgments will not be informative and useful in permanently changing contexts and limited ability to retrieve/obtain and process all relevant information on time. As a result, the best a decision-maker can do is to rank order the available choice options on each attribute and thus to construct an ordinal scale (see Stewart et al. 2006, for a formal model). Thus, cognitive agents can only make inferences about the attribute value of options by simply counting how many times each option is better or worse than another (e.g., the option that has never been worse off is obviously the best one to take).

Such evidence presents another challenge to the standard rational choice theory but also challenges descriptive theories of decision-making under uncertainty, including *configural weight models* (Birnbaum et al. 1999), *prospect theory* and *cumulative prospect theory* (Kahneman and Tversky 2000), and *rank-dependent utility theory*

(Quiggin 1993), which all assign a choice option, such as a risky prospect, with a value or utility that depends only on the attributes of that option.

Conclusion

To conclude, in the face of existing evidence, human evolved rationality is best interpreted as a rather local, instead of global, phenomenon, i.e., rationality assumptions typically apply locally, within a context. But, if the distribution of contexts across individuals is reasonably stable, then this could create stable overall behavior. As a result, most of the time, markets behave stably, and behaviors can look stable and consistent. Such stability is not guaranteed, as we have seen, if the context changes significantly (e.g., if new goods become available, or the market receives an exogenous shock, such as a supply shortage or a sales tax increase). This article shows how the standard focus in rational choice theory on consistency can also be derived out of knowledge of basic, evolved cognitive mechanisms underlying decision-making.

Individual differences in violence

Definition

Variability of aggression: human aggressive behavior varies on a number of dimensions. This variability is best understood through an interdisciplinary evolutionary approach.

Introduction

In one of the first assessments of the potential contributions of evolutionary psychology to the study of aggression, David Buss and Todd Shackelford (1997) propose an account of human aggression arising as the result of adaptive mechanisms that evolved in response to various challenges of social living. Buss and Shackelford point out that the perspective of evolutionary psychology reveals aggression to be multifaceted and to involve several underlying mechanisms responsive in varying contexts. As they say, their account predicts variability in aggression. There are several dimensions to this predicted variability. There is sexual dimorphism in human aggression, some populations are more aggressive than others, and there is variation in types of aggressive behavior in a given circumstance. The advantage to an evolutionary psychology approach is that it predicts the manifest variation in human aggressive behavior. Many alternate psychological accounts of aggression do not have the resources to account for this variation. The disadvantage to the evolutionary psychology approach outlined by Buss and Shackelford is that it does not provide explanatory leverage over local and specific cases of variation, such as three individual men's different responses to their spouse's infidelity, and it does not adequately explain why in some cultures violent behavior is required for social status, whereas in others such behavior leads to reputational damage (cf. Buss and Shackelford 1997, p. 617).

Evolutionary theory, broadly construed, provides many resources to account for variation in phenotypic traits, so an evolutionary approach to variability of human aggression holds promise. Evolutionary psychologists have adopted approaches that downplay, underplay, or ignore human phenotypic variation, and this is rightly seen as a problem (Cf. Confer et al. 2010). Human aggression takes many different forms – from subtle, nonviolent covert aggression in the work place, to violent physical aggression at a sporting event, and to deadly political aggression designed to facilitate social change. This entry reviews some work on three examples of human aggressive behavior: male-on-male aggression

within cultures of honor, female-on-female aggression, and intimate partner violence involving aggression toward the other member of a close relationship. All three cases present a great deal of variation, and explaining this variation is a task for any evolutionary science of human behavior. The varying evolutionary hypotheses for the relevant variation in each of these examples of human aggression are presented and contrasted, where applicable, with alternate accounts of the relevant variation. An evolutionary approach to human aggression is productive and useful, but proposed here is a broader-based interdisciplinary evolutionary approach than evolutionary psychology traditionally construed.

Male-on-Male Aggression in Cultures of Honor

A young man walks down a hallway at a large public university in the United States. As he reaches a narrow point in the hallway, another young male bumps the first and calls him an “ass-hole.” How does the bumped and then insulted young man respond? According to Dov Cohen, Richard Nisbett, and their colleagues, it depends. In particular, it depends on whether the young man is from the North or from the South in the United States. Cohen and Nisbett, in a series of experiments, set up just such a scenario where the first young man was a research participant and the second was a member of the research team in order to examine how young men from different geographic backgrounds responded to such an affront. While men from the North tended to respond to the bump/insult with amusement and little else, men from the South tended to respond with anger, and they also became more stressed (measured by increased cortisol levels) and more inclined toward future aggression (measured by increased testosterone levels) (Cohen et al. 1996).

Why? Why would young men from the South on average respond differently to a perceived slight than young men from the North? According to Cohen and Nisbett, the explanation comes from the presence/absence of a culture of honor, where adherents to a culture of honor are more inclined

toward responding aggressively to reputational affronts. A culture of honor, in turn, is more widespread in the South than it is in the North because of the different cultural-geographic-economic histories of those two regions. While the densely populated North brought with it readily available law enforcement that could quickly deescalate aggressive interactions, the more pastorally dispersed South meant law enforcement was often unavailable during aggressive encounters. So while Northerners grew accustomed to brushing off perceived slights because their personal resources were not threatened as long as law enforcement was nearby, Southerners developed a heightened response to perceived slights because their personal reputation for not tolerating challenges was the more immediate protection against threats to personal resources.

Shackelford (2005) explains the North-South group difference documented by Nisbett and Cohen with resources from evolutionary psychology. All men, Shackelford proposes, have an *evolved reputation maintenance mechanism*, which dictates how men respond to reputational challenges in an adaptive manner. That mechanism, however, is context sensitive because different responses are more/less adaptive depending on context; in particular, a contextual feature like the local economy will influence the threshold that must be met to respond to reputational challenges with aggression. Applied to the North-South group difference, the idea is that Northern and Southern men both possess the evolved reputation maintenance mechanism, but the unique economic history of the South (at least in comparison to the North) led to a lower threshold for triggering an aggressive response to reputational challenges because it was more biologically advantageous to respond as such.

Shackelford's appeal to evolutionary psychology, however, is not the only evolutionary explanation of the North-South group difference. As Stefan Linquist (2016) details, there are several other evolutionary explanations. A memetic explanation appeals to a purely cultural transmission of the trait in question. On a memetic reading, the culture of honor and its associated response to aggression are culturally transmitted in the South

regardless of any biological advantage; in short, it is the *culture* of the culture of honor that propagates the phenomenon long after the South has by and large abandoned a pastoral economy. Alternatively, there are also evolutionary explanations that employ interacting biological and cultural variables. Dual inheritance theory combines biological variables (i.e., genetically inherited predisposition) with autonomous cultural variables (i.e., socially learned behaviors), whereby each variable shapes the other. In contrast to the evolutionary psychological explanation, which takes the universal psychological mechanism to be triggered by some environmental exposure, the dual inheritance explanation takes the biological and cultural variables to coevolve.

It is important to keep in mind that all of the evolutionary explanations of the North-South group difference mentioned above are focused on explaining just that – the *group* difference, which is a difference between the averages of the individuals within the groups. But these group averages mask individual differences within the groups; not every Southern man responded to the insult with aggression, and some Northern men did respond with aggression. If, as is widely acknowledged, variation is a thing to be explained, then individual differences within group averages point to additional sources of variation that must be identified and incorporated into the explanations of the variation.

Female-on-Female Aggression

Aggression researchers have traditionally endorsed the view that men are more aggressive than women. This position is bolstered by the abundant evidence that men commit more murders than women and engage in more violent acts than women, such as assault (see, e.g., Daly and Wilson 1988). Work by researchers such as Anne Campbell (see, e.g., Campbell 1999) reveals that this is not the whole story on differences between male and female aggressive behavior. There is plenty of female same sex aggression that does not manifest in violent acts. Bjorkqvist et al. (1992) found that women are much more likely

than men to engage in aggressive acts such as excluding and spreading false rumors. For example, young women from many different cultures attack other women's sexual reputation and defend their own sexual reputation. Women and girls in many cultures label those perceived as promiscuous "slags," "tarts," or "whores." Such attacks involve verbal, indirect, or relational aggression. Adolescent girls are also involved in direct acts of violence, and these are much more likely to be directed at other girls or women.

A group of 15-year-old school girls are presented with a vignette describing another girl's exclusion by her friends and overhearing her friends "bitching" about her. Girls presented with the vignette were asked about the behavior, answering questions about whether it was common and whether or not it was hurtful. The girls reported that exclusionary behavior and "bitching" were extremely common. On exclusion, one participant said that when a girl approached them crying and seeking sympathy, other group members said "Don't let her in, 'cause she's a bitch and she spread rumors about us and everything. The last group she was in was our group" (Owens et al. 2000, p. 76). When asked how long ostracism can last, girls reported that cases can last three school terms, leading to a miserable existence for the victim. There is no question in the girl's minds that these exclusionary acts are hurtful to the victims. Such indirectly aggressive acts are widespread among teenage girls more so than direct acts of aggression such as tripping and slapping (Owens et al. 2000, p. 77). Teenage boys are more likely to engage in direct acts of aggression than their female counterparts (see, e.g., Bjorkqvist et al. 1992).

Why the difference in aggressive behavior in girls and boys? Many social science researchers attribute the differences to differences in social relations reinforced by socialization. Girls value intimate relations, whereas boys associate in larger groups and are more concerned with physical prowess and dominance relations (cf. Owens et al. 2000). In contrast, evolutionary psychologists, along with other evolutionary social scientists, argue that sex differences in aggressive behavior are grounded in biology. Much

evolutionary work on women's intra-sexual aggression characterizes the behavior as resulting from sexual competition or resource competition (Campbell 2013). Much male aggressive behavior is also attributed to resource competition or sexual competition, so the fact that the women's aggressive behavior is more likely to be indirect needs further explanation. The differences in type of aggressive behavior are accounted for by broader evolutionary theorizing about sex and reproduction (Campbell 1999, 2013). For example, differences in male and female parental investment lead to predictions that women will engage in less physically risky behavior than men, as they need to preserve their physical resources to tend their offspring (see, e.g., Taylor et al. 2000). It is important to note that such explanations are evolutionary and should be understood in terms of ancestral women's behavior and the selection pressures that shaped it rather than as proximal explanations of contemporary women's behavior.

Accounting for sex differences in aggressive behavior in terms of differential parental investment (among other mechanisms) only goes so far. First, the differences in aggressive behavior between men and women are not clear-cut. As noted above, Bjorkqvist's (1992) initial finding that there is a large difference between male and female aggressive behavior has been challenged (see, e.g., Archer 2004), leaving us with a picture of much more continuous variation. Second, there is clear variation within groups of women and men. Finally, there are cultural differences in women's intra-sexual aggression. Such variation could be addressed from an evolutionary perspective, but more theoretical resources are required than parental investment theory.

Male-on-Female Intimate Partner Violence

Intimate partner violence involves behaviors that cause physical, psychological, or sexual harm to other member(s) of a relationship; examples include hitting, forced sexual intercourse, intimidation, humiliation, and restricting access to financial resources (with multiple forms often

co-occurring). Women are most often the victims of intimate partner violence, and men are most often the perpetrators; in a WHO survey of ten countries, percentages of ever-partnered women who reported sexual violence by a partner at some point in their lives ranged from 6% in Serbia to 59% in Ethiopia (Organization 2012).

As the difference between women in Serbia and women in Ethiopia mentioned above reveals, there is a great deal of variation in intimate partner violence. Personal, relationship, and societal factors can all affect rates of intimate partner violence; low education is a personal risk factor both for being a victim of intimate partner violence and for being a perpetrator of it; economic stress and dissatisfaction with the relationship itself are both relationship-level risk factors; and societal factors include weak legal and social sanctions against intimate partner violence (Organization 2012). One societal factor that was discussed earlier within the context of male-on-male aggression and which is also relevant to intimate partner violence is a culture of honor. Researchers have repeatedly found that increased identification with a culture of honor coincides with increased tolerance for violence against partners; this increased tolerance is found in both the women and the men of the culture of honor societies (Vandello and Cohen 2003).

Intimate partner violence has long been on the radar of evolutionary psychologists. Indeed, in Buss and Shackelford's early review of human aggression, it was one of the seven adaptive problems for which they pointed to aggression evolving as a solution; the idea there was that male-on-female intimate partner violence was a product of jealousy and that emotion evolved in order to deter long-term mates from sexual infidelity (Buss and Shackelford 1997). Buss and Shackelford's explanation in part built off the earlier work by Buss and his colleagues on sex differences in jealousy; in species with internal female fertilization, males are challenged by uncertainty concerning the paternity of their offspring such that there is a risk that they invest significant resources in the care of offspring that are not their own, and so men's jealousy is directed more toward sexual infidelity, as opposed

to women whose jealous responses are primed more by emotional infidelity (Buss et al. 1992). The evolutionary psychology explanation of intimate partner violence, then, is that it is the result of jealousy, which is itself the product of an adaptive response to the problem of paternity uncertainty (Kaighobadi et al. 2009; Wilson and Daly 1996). The variation in intimate partner violence is in turn captured by way of the context sensitivity of the adaptive jealousy; it is deployed selectively depending on various personal, relationship, and social factors (Buss and Duntley 2011).

As with the discussion of male-on-male aggression earlier, however, the evolutionary psychology explanation of intimate partner violence is not the only evolutionary explanation available. Above, recall, Linquist (2016) also considered memetic and interactionist explanations, and similar considerations are relevant here. A memetic explanation of intimate partner violence draws attention to the culturally inherited features that contribute to the phenomenon. For example, Archer points to differences in gender empowerment as a prime societal factor that affects the prevalence of physical intimate partner violence in a culture: looking across a range of nations, as gender equality increases, the rate of female victims of intimate partner violence decreases, and the rate of male victims of intimate partner violence increases (Archer 2006). The memetic explanation here appeals to the culturally inherited social roles that men and women find themselves in and which dictate the social constraints under which they can behave in a society. A dual inheritance theory of intimate partner violence is worth considering too; the idea would be that some biological variable(s) such as inclination toward jealous aggression and some cultural variable(s) such as widespread societal tolerance for gender inequity coevolve.

Much of the research on intimate partner violence focuses on identifying between-group variation (usually at the nation level) and then seeks out group differences (such as prevalence/absence of a culture of honor or differences in gender equality) to explain that variation. But as with the previous two examples, within-group

variation is also striking and important to both highlight and explain. Within-group variation points to additional causes of the phenomenon in question that cannot be attributed to either universal psychological mechanisms or to cultural-wide factors alone. A striking example of this comes from Vandello and Cohen (2003), who discuss differences in perceptions of women's honor in Saudi Arabia, where it was found that concern with women's honor was most pronounced at the very highest and very lowest socioeconomic levels; a focus on traditional extended family arrangements is most important at the highest and lowest levels of the social hierarchy in Saudi Arabia but less so among the middle strata of that society, and so it was this unique and local factor that produced a bimodal distribution within just one society.

Evolutionary Approaches to Variation in Aggressive Behavior

There is clearly variation in human aggressive behavior. The cases above illustrate variation in specific types of aggression between different geographical groups and between men and women. Evolutionary psychologists, as well as other evolutionary social scientists, reject many purely cultural accounts of human behavior, such as aggression, arguing that evolutionary approaches are superior. Campbell typifies this approach when she says "the psychology of aggression, prior to the advent of an evolutionary perspective, was often a fragmented and incoherent enterprise. [...] Evolutionary theory provides a coherent way of thinking and talking about aggression in functional terms" (2005, p. 646). There is less agreement about the role of evolutionary thinking in accounting for *variation* in behavior. Some evolutionary psychologists see evolutionary approaches to accounting for variation as outside their purview: "Behavioral geneticists, through twin studies and comparisons of kin raised together and apart, explore the extent to which *differences* between individuals are accounted for by *differences* in their genes. [...]. In contrast, evolutionary psychologists primarily

explore the design of the universal, evolved psychological and neural architecture that we all share by virtue of being human" (Tooby and Cosmides 2005, p. 39), where others, such as Shackelford (2005), clearly take variation in behavior to be amenable to evolutionary explanation and take evolutionary psychology as having an important role to play in explaining such variation.

As noted above, Lindquist (2016) lays out several evolutionary approaches to account for variation in male-on-male aggression in and outside cultures of honor. He adds dual inheritance theory (gene-culture coevolution) and cultural niche construction to evolutionary psychologists' preferred adaptive mechanism approach. There are many more evolutionary approaches to accounting for human behavioral diversity and hence variation in aggression. Gillian Brown et al. (2011) present alternate evolutionary approaches to human behavioral diversity including those mentioned here but adding human behavioral ecology and different approaches based on the study of genetic diversity. While Tooby and Cosmides (2005) appear to want to distance evolutionary psychology from behavioral genetics, a more encompassing evolutionary approach to variation in human behavior would include as many evolutionary resources as possible. Behavioral geneticists provide many tools for examining human variation and variation in human aggression in particular. Ian Craig and Kelly Halton (2009) assess research to date on the genetics of human aggression, and while they find little evidence for genetic loci with major effect size, they offer helpful explanations of variation in human aggressive behavior in terms of gene/environment interactions (see Tabery 2014 for a detailed discussion of gene/environment interaction and human aggressive behavior). While some evolutionary psychologists defend the view that evolution only produces uniformity or universality of traits, many evolutionary theorists present and defend accounts of the evolution of variation. For example, John Maynard Smith used aggression as a case study in his models of selection for variation in behavior (Maynard Smith and Harper 1988). There are

many other examples of evolutionary processes leading to variation such as disruptive or diversifying selection, heterozygote dominance, and selection for phenotypic plasticity (see, e.g., Pavlicev et al. 2011).

Conclusion

An interdisciplinary approach to accounting for variation in human aggressive behavior is recommended here (cf. Brown et al. 2011; Longino 2013). Here is a sample of the relevant disciplines: anthropology, endocrinology, evolutionary anthropology, evolutionary psychology, and sociology. Such an approach takes on board a wide range of evolutionary thinking but also allows for purely cultural accounts of some variation in aggressive behavior where the evidence best supports such accounts. At this juncture there appears to be little to be gained from ruling out any evolutionary approaches to accounting for variation a priori. The examples of variation in aggressive behavior discussed above could be amenable to a number of evolutionary explanations, and several alternate evolutionary explanations could work together to account for the relevant case. There are debates between researchers on the evolution of human behavior from different theoretical backgrounds, for example, evolutionary psychologists and behavioral ecologists disagree over the appropriate evolutionary approach (see, e.g., Downes 2001). Such disagreements need not necessarily disrupt an interdisciplinary approach. As Brown et al. (2011) reveal, many researchers who appear to be at odds can easily accommodate each other's evolutionary approaches as illustrated by Hillard Kaplan and Steven Gangestad's (2005) combination of evolutionary psychology and life history theory.

An obvious objection here is that the evolutionary psychology approach, involving an adapted mechanism and its differing responses to different environmental or cultural conditions, provides all the explanation required for variation in aggressive behavior. This approach appears to load too much onto cultural context where some

variation could be explained by alternate evolutionary means. For example, explanations of variation in female-on-female aggression appeal to mechanisms underlying sexual and resource competition and the different ways these mechanisms are evoked in different cultural circumstances. Such an approach could be usefully supplemented with a gene/environment interaction or a cultural niche construction approach, depending on where the evidence leads. These further explanations may not exhaust the variation in question and may require supplementation from endocrinology and so on (see, e.g., Cashdan 2008 on variation in women's waist/hip ratios). As revealed in the discussion of alternate ways of accounting for variation in culture of honor aggression, appealing to evoked culture can prematurely close the door on alternate evolutionary explanations of the relevant variation (cf. Linquist 2016). An interdisciplinary approach is preferable to an attempt to force one type of evolutionary explanation on a wide diversity of evidence.

Variance in Female Reproductive Success

Katherine Starkweather

[Reproductive fitness](#)

Definition

When some females in a population have more surviving offspring than other females in the population.

Introduction

Variance in reproductive success occurs when some individuals in a community have more surviving offspring than others and is typically discussed as a result of sexual selection (Trivers 1972). Sexual selection is a competition within one sex for sexual access to members of the opposite sex and a differential choice by members of one sex to breed with particular members of the opposite sex. The traditional view among evolutionary biologists is that males compete against each other for access to females, and females are

coy and choosy in determining who they will mate with. In his experiments with *Drosophila melanogaster*, Bateman (1948) provided evidence for these conjectures and also showed that male reproductive success varied much more than female reproductive success. That is, many more males than females produced zero surviving offspring. This trend has been found in a number of mammalian studies since then (e.g., Clutton-Brock 1988).

Constraints on Reproduction

One explanation for the trend has to do with biological constraints faced by each sex (Williams 1966). For male mammals, production of sperm is relatively unlimited and energetically cheap. Also, necessity of males to the reproductive process ends after the deposit of sperm in the female. The result is that male reproductive success is limited only by the number of mates one male can acquire. Mammalian females face much greater biological constraints than males. First, production of eggs is energetically much more costly than production of sperm. And second, the number of eggs a female produces in her lifetime is limited at birth. Third, the time required for gestation makes up a significant portion of females' adult life span, and gestation is energetically very costly. Lactation also requires investment of time and energy that males are not encumbered with. Therefore, female fertility is time and energy limited, and the result is that the total number of offspring one female could have in her lifetime is far fewer than the total number one male could have in his.

Of course, a number of factors mitigate these constraints for both males and females, including individual reproductive viability, the operational sex ratio (OSR) of a group, and a group's social structure. The OSR is the ratio of males to females who are ready to mate in a population at a given time (Emlen and Oring 1977). A male-biased OSR (one with more males ready to mate than females) will restrict the number of mates

available to males and will result in some males not mating and others mating polygynously. Monogamy is another mitigating factor, which limits a male's lifetime reproductive success to his female partner's reproductive potential and often results in extremely low variance for both partners.

In traditional human populations, most mating occurs within socially sanctioned marriages, and the marriage systems practiced in any given society can either be biologically imposed – by the OSR or by the resource availability in environments – or socially imposed. One common response to excess women in a group is polygynous marriage and increased variance in male reproductive success. When there are excess men in a group, polyandrous marriage is sometimes a response (Starkweather and Hames 2012), but societies often come up with other solutions for having more men than women in a population like sending those men to war or the priesthood.

Female Multiple Mating and Reproductive Variance

Sarah Hrdy (1980) challenged the idea of the “coy female” when she observed female langurs mating with males outside of their own group. Hrdy (1980) suggests that females across species use multiple mating as a way to improve their own reproductive fitness, and evidence certainly exists in support of this hypothesis (e.g., Jennions and Petrie 2000). The question is, though, if multiple mating for males results in variance in male reproductive success does multiple mating for females result in variance in female reproductive success with some females not mating at all and those who mate multiply having more offspring than those who mate singly.

There is some evidence from the animal world that suggests multiple mating by females does result in more variance in female reproductive success (see Clutton-Brock 1988). Among human females, multiple mating can occur via serial monogamy, extramarital affairs, or polyandrous marriage. Evidence from societies practicing serial monogamy shows levels of variance for

men that is closer to polygynous societies than monogamous, suggesting that some men monopolize multiple women. This number may be misleading, though, because as Brown and colleagues (2009) point out, both men and women in serially monogamous couplings are mating with multiple partners. Among women who participate in extramarital affairs, it can be difficult to study variance based on these matings because women in many cultures do not discuss these socially unacceptable relationships. One society for which reproductive success is being studied in relationship to extra-pair affairs is the Himba of Namibia. Though variance is not specifically examined, Scelza (2011) shows that women who have extra-pair births tend to have more births in total over the course of their lifetimes.

It is also unclear to what extent polyandrous unions result in increased variance in reproductive success for women. From a biological standpoint, women in polyandrous marriages should not have any greater reproductive success than women in monogamous marriages, because the marital unit is limited by the woman's reproductive ability in both cases. We do know that additional husbands (or fathers, depending on the society) can help keep children alive in some Amazonian cultures where partible paternity is practiced (e.g., Beckerman et al. 2002), which enhances women's reproductive success. However, what does not seem to be true among societies that allow polyandry is that some women in the society do not marry or reproduce at all. This is probably due to the facts that (1) in nearly all societies where polyandry is allowed, monogamy and polygyny are also practiced and (2) for most societies that allow polyandry, it is not the most common form of marriage nor is it the most preferred (Starkweather and Hames 2012). It is particularly interesting that in one of the cases where polyandry is the most common and most preferred form of marriage – in Humal, Nepal – some women do not reproduce at all, others do not reproduce until later in life, and those who marry polyandrously at an early age have the highest reproductive success, therefore accounting for a great deal of within society variance in women's reproductive success (Haddix 1999).

Conclusion

The few human examples offered here suggest that it is indeed possible for women's reproductive success to vary within societies. In some cases, women in certain circumstances can have many more surviving children than women in other circumstances. Across traditional societies what does seem uncommon is for women who are reproductively viable to not reproduce at all. Restricting some women from reproducing appears to only happen rarely and when it is socially sanctioned. More research needs to be done on the conditions that allow some women to out-reproduce others as well as on the reproductive benefits for women engaged in multiple mating to fully understand how and when greater levels of variance in women's reproductive success occur.

Ventral Stream, The

Robert L. Whitwell

Department of Psychology, University of British Columbia, Vancouver, BC, Canada

Synonyms

Inferior longitudinal fasciculus; Occipitotemporal projection system; Ventral visual pathway

Definition

A parallel, hierarchically organized series (i.e., “stream”) of interconnected structures in the occipital and temporal cortex (TC).

Introduction

The ventral visual stream refers to a parallel series of relatively hierarchically organized cortico-cortical projections that arise chiefly from extrastriate visual areas of the occipital cortex and innervate structures in and around the inferior TC (Kravitz et al. 2013). Neighboring cortical structures of the ventral visual stream are typically heavily reciprocally connected, in line with a hierarchical organization of progressive abstraction of visual input. Ventral stream structures, like all others in primate cortex, are typically delineated according to their morphology, connectivity, and functional properties across microscopic and macroscopic scales of observation and show close homologies across human and nonhuman primates (Kravitz et al. 2013). However, unlike cells in “early” areas of the occipital cortex, visually sensitive cells in the TC possess large receptive fields, a coarse retinotopic organization, and show slower visual onset locked activity.

Furthermore, the responses of neurons in ventral stream structures are driven by complex stimulus features, conjunctions of those features, or the qualitative properties of the visual stimulus (Kravitz et al. 2013).

Subcortical Visual Input to the Dorsal Stream

Geniculostriate Visual Pathway

The dominant source of retinal input into both the ventral and dorsal streams comes through early visual cortex via the dorsolateral geniculate nucleus (dLGN). The dLGN receives visual input directly from retinal ganglion cells and indirectly via another direct recipient of retinal ganglion cell input, the superior colliculus (SC). Visual input from the dLGN to the occipital cortex arises from different populations of neurons. The best studied of those populations are the parvocellular (P) and magnocellular (M) cells, which occupy different layers of the dLGN (Kaplan 2004). Relative to M cells, P cells possess slower conduction velocities, longer response latencies, longer responses, smaller visual receptive fields, sensitivity to chromatic differences, and greater sensitivity to high spatial frequencies (Kaplan 2004). The P and M cells send parallel convergent and divergent projections to striate (primary) visual cortex (V1). This pattern of connections continues on through the many extrastriate cortical areas, forming parallel, though interconnected, subpathways within the ventral and dorsal streams (Ferrera et al. 1994; Kaplan 2004). The ventral stream receives relatively balanced input from the P and M subpathways, whereas the dorsal stream receives a relatively stronger input from the M subpathway (Ferrera et al. 1994). One major extrastriate target for the P and M pathways is the ventral stream “tributary,” V4. Neurons in V4 show robust activity despite inactivation of only one of either the P or M subpathways (Ferrera et al. 1994).

Extrageniculostriate Visual Pathway

The connections of the ventral and dorsal stream with the pulvinar also differ. The medial, central, and posterior nuclei of the inferior division of

the pulvinar (PI) receive direct visual input from retinal ganglion cells. The posterior and central-medial nuclei of the PI receive secondary visual input from the superficial layers of the SC. Of these substructures, the posterior and central-medial nuclei of the PI project to cortical area V4, a ventral stream “tributary.” V4 also receives input from the ventrolateral nucleus of the lateral pulvinar, but it is less clear whether this input is capable of driving visual responses in V4 in the absence of early visual cortex (Kaas and Lyon 2007).

Extrastriate Visual Cortical Area “Tributaries” to the Ventral Stream

The extrastriate visual areas that send major projections to inferior TC structures of the ventral stream are V2, V3, and V4. V2 lies just posterior to and on the posterior banks of the lunate sulcus (LS) and inferior occipital sulcus (IOS). The CO-rich thin and CO-poor interstripe regions of V2 project to the V4 and the ventral stream structure TEO in the inferotemporal cortex (Ungerleider et al. 2008). V3 lies anterior to V2 in the posterior bank and fundus of the LS and the IOS. V4 lies anterior to V3 in the anterior bank of the LS and prelunate gyrus. V4, V3, and V2 receive major feedforward input from V1, which is the principal cortical entry point for visual input and occupies much of the posterior occipital cortex. Although V4 predominantly projects to ventral stream structures TEO and TE, the subregion which represents the peripheral field also projects to dorsal stream structures in the lateral intraparietal sulcus (Ungerleider et al. 2008).

Cortical Connections of the Visual Inferotemporal Cortex

Intrinsic Connections

Visually responsive inferior TC is comprised of three major cytoarchitecturally defined regions, TEO, TF, and TE and its various subdivisions (see Fig. 1). TEO is anterior to V4, occupies the caudal region of the lateral and ventrolateral surface of

temporal cortex in the middle and inferior temporal gyri, and is bordered by the superior temporal sulcus (STS). TE is anterior to TEO, occupies the rostral region of the lateral and ventrolateral surface of the temporal cortex in the middle and inferior temporal gyri, is bordered dorsally by STS, and area TG at the temporal pole forms its anterior border. Area TF is located on the medial side of the inferior TC and occupies a caudal region of the hippocampal gyrus. Neurons in a caudal subregion of TF anterior to ventral V4 and medial to TEO respond to visual stimuli (Boussaoud et al. 1991). Ventral stream structures, like most others in cortex, are interconnected with neighboring ones. TF is reciprocally connected with V4, TEO, and TE (Suzuki and Amaral 1994). TEO is strongly reciprocally connected with V4 and to a lesser extent V3 and V2 (Ungerleider et al. 2008). TE is reciprocally connected with TEO and receives projections from V4 (Ungerleider et al. 2008). Neurons in TEO vary widely in the sizes of their receptive fields which helps give rise to the coarse retinotopy observed across TEO with the transition from upper to lower visual field generally oriented in a rostral-to-caudal direction (Boussaoud et al. 1991).

Cortical Output Pathways

Medial Temporal Lobe Pathways

The medial temporal lobe (MTL) includes the amygdala, hippocampus and cortical structures located in the entorhinal, parahippocampal, and perirhinal cortex. Although the MTL is multisensory and plays a critical role in declarative memory, some of its cortical structures are reciprocally connected with visual ventral stream structures V4, TEO, and TE (Saleem and Tanaka 1996; Suzuki and Amaral 1994; Webster et al. 1991). TEO receives projections from area TG, perirhinal areas 35 and 36, and parahippocampal areas TF and TH. TE is reciprocally connected with perirhinal cortical areas 35 and its anterior neighbor area 36, both of which border TE medially and both of which are critical sources of visual input to the hippocampus. TE is also reciprocally connected with entorhinal cortex area 28, which

major sulcal landmarks. The connections from ventral stream structures to the dorsolateral, ventrolateral, and ventromedial prefrontal cortex and the medial temporal lobe are color-coded

is located medial to perirhinal cortex, and area TG, which is located on the inferior temporal pole, just anterior to TE. Both TF and its medial cortical neighbor TH are reciprocally connected and each projects to TE (Suzuki and Amaral 1994).

Dorsolateral, Ventrolateral, and Ventromedial (Orbitofrontal) Prefrontal Pathways

Ventral stream structures TEO and TE show different though partially overlapping connections to a number of structures in different regions of the prefrontal cortex. Dorsolateral area 8 in the prearcuate gyrus is reciprocally connected with both TEO and TE. Ventrolateral area 45, on the rostral bank of the inferior limb of the arcuate sulcus, and area 12, on the inferior convexity of the prefrontal cortex, are each reciprocally connected with both TEO and TE. TE, but not TEO, is reciprocally connected with ventromedial areas 11 and 13 on the orbital surface (Webster et al. 1994).

Function

The functions of TEO and TE are to maintain object constancies for visual perception and visual memory and to service the complex cognitive functions associated with their cortical targets in the prefrontal cortex. Areas V4 and TEO, but not TE, are organized retinotopically. The neural response latencies and size of the receptive fields increase moving from V4 to TEO. Moving from TEO to TE, the size of the receptive fields increases sharply in many, but not all, neurons and will frequently include the foveal area in the ipsilateral visual field (Boussaoud et al. 1991; Kravitz et al. 2013). Importantly, TE still possesses many cells with small receptive fields, which suggests that this area signals, among other things, object position (Fujita 2002; Kravitz et al. 2013). Furthermore, the receptive fields of neurons in V4 and TEO are often centred beyond the foveal area and include a portion of the periphery, suggesting. Again, that these cells signal

object position (Fujita 2002). Generally, neurons in V4, TEO, and TE do not respond to simple visual stimuli such as linear grating, edges, or bars (Fujita 2002). Neurons in V4 are selective for color, object form, or conjunctions of the two (Ungerleider et al. 2008). Neurons in V4, TEO, and TE are sensitive to binocular disparity, including the gradient of disparity which can signal the depth of an object relative to fixation (Fujita 2002). Lesions to TEO have long been associated with deficits in pattern discrimination, whereas lesions to TE are associated with deficits in acquiring reward-contingent discriminative object-response relationships (Webster et al. 1994).

In line with the notion that ventral stream structures are critical for the establishment of perceptual object constancies, TE neurons show a remarkable level of invariance in object shape selectivity despite spatial transformations of stimuli such as a change in position, luminance, texture, motion, binocular disparity or occlusion, mirror, and figure-ground reversals, and changes in the background (Fujita 2002). Like much of visual cortex, TE neurons are organized into “columns” that span the different layers of cortex. Typically, neurons within a column show a moderate level of correlation in their responses to similar objects and similar degrees of retinal disparity than do those in different columns (Fujita 2002). The topographical distribution of columns is patchy, which presumably reflects an absence of any advantage for topographically organizing object qualities and identity.

The connections of TEO and TE to MTL and the prefrontal cortex serve higher order cognitive functions associated with those regions. The visual input to MTL is critical for storing new long-term memories of object quality. Connections between TE and MTL facilitate the use of visual object information for encoding places and landmarks in these structures critical for the distal control of spatial navigation. The dorsolateral and ventrolateral prefrontal cortex are associated with spatial and object working-memory, respectively. Ventromedial prefrontal cortex is associated with the evaluation and learning of stimulus-reward contingencies and the establishment of valence or biological relevance (Kravitz et al. 2013).

Conclusion

Proposals concerning the nature and content of the operations performed in the ventral stream are active areas of research and have been for decades. The ventral stream is a hierarchical network of parallel cortical structures in the occipital and inferior TC of the primate brain that operates at the interface of memory and other higher-order cognitive processes like working memory and reward evaluation. Contemporary accounts focus on a number of different roles which are perhaps best summarized as *mnemonic* and *evaluative* for object and scene quality. These functions ultimately serve the distal (or indirect) control of behavior, as opposed to the dorsal stream’s more proximal or direct control over object-directed behavior. Accordingly, target structures for ventral stream output are critically involved in recognition and identification, planning and goal-formation, stimulus-response relationships and their reward values, biological relevance, and long-term, and working forms of visual memory (Kravitz et al. 2013).

Definition

The use of verbal insults to devalue a woman's mate value relative to one's own mate value.

Introduction

Verbal derogation is a strategy commonly used by women who are in competition for male attention. When women use this strategy, they say things about another woman in an attempt to lower the other woman's mate value. Verbal derogation can take the form of direct aggression, such as when someone yells at another person (Bjorkqvist et al. 1992). However, women's verbal derogation typically takes the form of indirect aggression, such as gossiping and rumor spreading. Women's derogatory comments about other women have

three major themes: women's appearance, promiscuity, and fidelity (Buss and Dedden 1990). Specifically, women are likely to verbally derogate other women by criticizing the way they look or by saying that they are "easy" or that they sleep around on their partner.

Indirect Verbal Derogation Versus Direct Verbal Derogation

Women are more likely to engage in indirect aggression, such as gossiping, than they are to engage in direct aggression, such as yelling at someone (Campbell 1999). One reason for this discrepancy may be a result of women typically holding the role of primary caregiver. A physical injury could hinder a woman's ability to care for her children, so the risk of bodily injury may motivate women to favor indirect aggression over direct forms of aggression (Campbell 1999). Although verbal derogation is not inherently physical, one of the top reasons listed by women for getting into physical altercations is that they were verbally insulted by another woman (Campbell 1986). Avoiding all types of direct aggression, verbal or physical, may be a strategy women use to avoid physical harm. Unlike direct verbal derogation, indirect verbal derogation can be performed covertly (e.g., gossiping behind someone's back). Thus, this indirect strategy may help women avoid the social and physical repercussion that are likely when one directly aggresses against another person.

Efficacy of Competitor Derogation

Two strategies commonly used in intrasexual competition are self-promotion and competitor derogation. When women try to enhance their mate value through behaviors such as wearing makeup or attractive clothing, they are engaging in a self-promotion strategy (Schmitt and Buss 1996). When women try to decrease other women's mate value relative to their own through behaviors such as criticizing someone's appearance or sexual history, they are engaging in a

competitor derogation strategy. Overall, derogation strategies such as verbal derogation are perceived as less effective than self-promotion strategies (Schmitt and Buss 1996). However, men rated a woman's physical appearance lower after a rival verbally derogated the woman's appearance (Fisher and Cox 2009). This effect was more pronounced when the derogatory comments came from an attractive rival than when they came from an unattractive rival.

Women who have been targets of indirect aggression have more negative self-perceptions than women who have not been targets (Paquette and Underwood 1999). Ostracism (a potential consequence of being verbally derogated against) has been linked to aggression and low self-esteem (Twenge et al. 2001). These outcomes suggest that verbal derogation does not simply lower people's perceptions of a rival's mate value; derogation also lowers a rival's self-perceived mate value.

Conclusion

Verbal derogation is a strategy in which women verbally insult another woman in an attempt to lower the mate value of the other woman relative to their own mate value. The most common traits that women derogate are other women's appearance, promiscuity, and fidelity. Women are more likely to engage in indirect derogation than direct derogation, and evidence suggests that verbal derogation may be an effective mate competition strategy.

Verbal Derogation Among Women

Jaimie Arona Krems
Arizona State University, Tempe, AZ, USA

Synonyms

Gossip; Indirect aggression; Mating competition; Relational aggression; Social aggression

Definition

When women spread information about other women (i.e., targets) to decrease those targets' social desirability.

Introduction

Why might women call other women “ugly,” “sluts,” or “bitches”?

When women compete with one another, they are particularly likely to use indirect tactics of aggression (Vaillancourt 2013). One such tactic is verbal derogation, whereby a woman spreads information that can decrease a potential rival's social desirability (Buss and Dedden 1990; McAndrew 2014; Fisher 2004). Such derogation often takes the form of gossip, which is typically engaged in covertly – behind the target's back.

A Function of Derogation

Most research on women's derogation of other women focuses on its use in competition for mates, rather than competition for same-sex allies or other resources. In mating competition, one potential function of such derogation is to make the target seem a less desirable romantic partner (Fisher 2004; Hess and Hagen 2006). Women may thus use verbal derogation to exclude perceived rivals, severing rivals' existing relationships and/or impairing their ability to form new ones, and ultimately decreasing that rival's reproductive fitness.

Derogation: Targets and Content

The typical content of women's verbal derogation fits nicely with this proposed function as a tool of women's mating competition. In prospective mates, men value fertility (often indexed as youth and physical attractiveness), fidelity, and – particularly for longer-term relationships – also nurturance (Buss and Schmitt 1993; Shackelford et al. 2002). Women typically derogate a target's physical attractiveness (e.g., “she's ugly”), fidelity (e.g., “she's a slut”), or nurturance (e.g., “she's a bitch”; Buss and Dedden 1990; Hess and Hagen 2006). Additionally, jealousy in these domains (e.g., physical attractiveness) is known to spur women's intrasexual derogation (Owens et al. 2000).

That women target strong rivals for mates also supports this proposed function. Highly attractive or seemingly promiscuous women are frequent targets of women's derogation (e.g., Vaillancourt 2013). Interestingly, these frequent targets may possess unique defenses against victimization (Krems et al. 2015).

Derogation: Benefits and Costs

In terms of effectiveness, women's intrasexual derogation may maximize harm to rivals while minimizing the risk of retaliatory aggression. Derogation may curtail targets' mating opportunities and/or reproductive fitness (e.g., Vaillancourt 2013). For example, accusations of promiscuousness are difficult to refute and can impair a woman's ability to form long-term relationships (Buss and Schmitt 1993; Hess and Hagen 2006). To the extent that derogation successfully disrupts a woman's relationships whether romantic or platonic it may impair her fecundity, as in nonhuman primates. Some perpetrators, however, may be more effective derogators than others; physically attractive women more effectively influence men's judgments of other women's attractiveness (Fisher and Cox 2009).

Verbal derogation is also relatively low cost. For example, gossip often allows gossipers to remain anonymous; even known perpetrators may claim the aggression was unintentional (e.g., "I meant your dress was 'scandalous' in a complimentary way"). This may decrease the likelihood of retaliation, rendering women's verbal derogation a high-impact and low-cost tactic of mating competition.

Conclusion

Verbal derogation may be an effective tactic in women's intrasexual competition.

Synonyms

Denominalization and nominalization; Zero conversion

Definition

To verb a noun is to create something of the verbal category from a nominal; to noun a verb is to do the reverse.

Introduction

Verbing and nouning are ways to introduce neologisms. The process, also called **denominalization** and **nominalization**, respectively, can be achieved by **compounding**, e.g., forming the verbs “to back up” or “to pig out” by combining a noun with some other term. It can also be achieved by **morphological derivation**, especially via affixation. In the noun → verb direction, the English “incentivize” and “declutter” are verbs which are derived morphologically from the nouns “incentive” and “clutter,” respectively. By the same token, the French “brosser” (to brush) comes from the noun “brosse” (brush), just as the Spanish “cepillar” comes from “cepillo.” Going in the verb → noun direction, in English, “suckage” and “singing” are nouns which derived from verbs by means of adding suffixes. Similarly, in Dagaare, a language from Ghana and Burkina Faso, the nominal “zoobu” (the act of running) is derived morphologically from the verb “zo” (to run); “gaabo” (departure) is derived from “gaa” (to go), while “waabo” (arrival) is derived from “wa” (to come), all by adding the appropriate suffix.

Why Are Verbing and Nouning Important for Language Evolution?

A subvariety of verbing and nouning, one of special interest when it comes to language evolution, is **conversion**, also known as **zero derivation**. Here, there is a “functional shift” without any change in surface form. All of the following arose via verbing of the zero-derivation type: “to google,” “to parent,” “to medal,” “to access,” “to trend,” “to bookmark,” “to email,” “to friend,” “to beer,” “to conference,” “to impact,” “to door,” “to showcase,” “to host,” “to input,” and “to blog.” And the nouns in “The new *hire* made a big *ask*, but it was an epic *fail*” all derived from verbs, but without compounding or the addition of affixes – that is, all arose through zero-derivation nouning. To come at the point another way, the hallmark of a noun-based verb, birthed by this particular method, is that speakers apply regular inflection directly to the bare form: in English, one adds “-ed” for the past and perfect form and “-ing” for the progressive and the gerund. (Notice, e.g., that the past tense of “to grandstand” is “grandstanded,” deriving immediately from the corresponding noun. As Prasada and Pinker (1993: 46) point out, it is not “grandstood.”) Similarly, in the verb → noun direction, one simply adds a determiner (such as the definite or indefinite articles “the” or “a”), a plural marker, or an adjective to the tenseless verbal form: “several good *reads*” and “a big *get*.” It is this latter zero-derivation subvariety which is most typically called “verbing and nouning.”

Verbing of the zero-derivation kind, i.e., without modification of the surface form, is especially a feature of languages which are not highly inflected. Thus English, whose verbal morphology is comparatively impoverished, allows it quite freely. In contrast, to create a new verb from a noun in French or Spanish, say, the new form must end in one of the three possible verbal paradigms (whether “-re,” “-ir,” or “-er” in French or “-ar,” “-er,” and “-ir” in Spanish). Hence their neologistic verbs will (almost invariably) have a different surface form than the source nouns, for instance, colloquial spoken French has “googler”

and “texter,” rather than just “google” and “texte,” and Spanish has “googlear.”

Are Prescriptive Grammarians Right to Be So Hostile to Verbing and Nouning?

The evolution of a language, especially in a free and rapid way, typically raises prescriptive hackles. Verbing and nouning of this zero-derivation sort is no exception. Pundits and bloggers complain that the usages are just business speak and technobabble. They find the coinages pointless. (Why use “epic fail” instead of the existing “failure”? And who needs “to impact”? They may even accuse ordinary speakers of a grammatical gaffe: the untutored are confusedly using nouns as verbs and vice versa! Linguists, in contrast, tend to be skeptical about such complaints. The process is not novel and is not tied exclusively to business speak or technology. The substantives in “a long *run*,” “a refreshing *swim*,” and “a pleasant *drive*” all started life as verbs, but are now wholly uncontroversial as nouns. The verbs in “to *stomach* his complaints,” “to *finger* a suspect,” “to *head* a committee,” and “to *elbow* a player” all arose through zero derivation from names of body parts; the verbs “to boycott,” “to lynch,” and “to gerrymander” all came from proper names of notorious figures, and “to ski,” “to bicycle,” and “to skate” all began life as names of sporting gear. (Pinker (1995) estimates that fully one fifth of English verbs arose through “verbing,” specifically via conversion. See also Clark and Clark (1979) and Luu (2016)). As Zwicky (2009) notes, moreover, the neologisms typically do not mean exactly what preexisting alternatives do, because of changes to connotations, to associated imagery, and to **register** (e.g., the level of formality or technicality of the word). Finally, these are not grammatically paradoxical cases of, say, nouns being conjugated and verbs taking plural endings. They are cases of new nouns/verbs being created – cases, that is, not of perverse misuse of the existing tongue, but of the language itself evolving.

Conclusion

In sum, verbing and nouning are linguistic processes for creating neologisms of a particular sort. The subvariety of greatest interest, characteristic of languages like English with quite simple verbal morphology, involves taking an old lexical item belonging to one word class and creating a new one – whether noun → verb or verb → noun – without changing the surface form. The process, known as conversion or zero derivation, leads to especially fast and efficient evolution of the language, with new coinages emerging and spreading seamlessly (particularly when certain pragmatic constraints are met (see Kaminski 2010; Luu 2016). While some prescriptive writers disparage this particular kind of language change, linguists find their reasons unpersuasive.

Definition

An unfortunate person who suffers from some adverse circumstance.

Introduction

Prior to the 1960s, criminological inquiry primarily centralized upon offender/criminal characteristics; negating situations, behaviors, and characteristics associated with victimization. While researchers had previously attempted to develop victim typologies with the use of law

enforcement data, criminologists were ultimately unsuccessful in their typological endeavors (Mendelsohn 1976). However, in the 1960s the first self-report victimization survey was developed and conducted allowing researches insight into what is now known as the dark figure of crime (Reiss 1967). After examining and refining methodological problems associated with the original survey, the first national level annual offender/victim analysis was implemented (National Crime Survey 1973; Barnes, Seepersad, Wilkis, & Wortley, 2016).

Since the development and implementation of the National Crime Survey (1973), an increase in criminological and psychological victim-based research has been observed. Said research indicates clear differentiation among victimization risk based upon individual/lifestyle characteristics. Characteristics correlated with risk of victimization include, but are not limited to, an individual's age, gender, ethnicity, social economic status, and peer network (Garofalo 1987). Specifically, males, minorities (i.e., African Americans), persons living in low socioeconomic neighborhoods, and adolescents are found to be at higher risk for experiencing personal and property victimization, with the highest rate of victimization occurring among African American males ranging from 14 to 24 years of age (National Crime Victimization Survey 2016).

Historically, the offender-victim relationship has been portrayed with males committing the majority of criminal acts with females possessing the greatest risk for victimization. However, national crime statistics indicate a unique relationship between offending and victimization risk with males being the most represented among both populations (excluding sex crimes) (National Crime Victimization Survey 2016).

Although not originally intended to differentiate by gender, both macro and micro-level theories have attempted to explain the variation among victimization risk. Multiple theories have investigated the relationship between gender and victimization from an offender – victim overlap perspective (Lauritsen and Laub 2007). Offender-victim overlap models focus on the relationship between offending behavior and victimization from a structural characteristic background,

spotlighting similarities among offender and victim attributes (Baumer and Lauritsen 2010).

Three theoretical approaches aiding in the explanation of the offender-victim overlap are lifestyle/routine activities theory, deviant lifestyles theory, and self-control theory (Jensen and Brownfield 1986; Schreck et al. 2008). For instance, Hindelang's (1976) "principle of homogeneity" focuses on the theoretical link between offending behavior and victimization, noting that certain behaviors may increase the potential for victimization.

Hindelang's (1976) theory of integrated lifestyle exposure was one of the first theories to focus on personal victimization and the differences therein. The theory of integrated lifestyle exposure was developed for the purpose of explaining the unequal distribution of victimization among various persons with differing backgrounds. Background characteristics include an individual's age, race, sex, income, marital status, social affiliation, etc. Furthermore, Hindelang (1976) proposed the idea that an individual's background could affect his/her potential achievements, reaction, and adaptation to novel stimuli, professional activities, and vocational activities. These individual background differences were theorized to result in observable lifestyle differences and purported to be indicators of an individual's daily routine.

Differences in lifestyle activities were believed to affect an individual's rate of exposure to high risk situations and/or environments. For instance, adolescent males were noted as having a higher frequency of unstructured nightly routines, spending more time in high-risk areas, while lacking the presence of parental or social control, thus increasing their exposure to offenders and the potential for victimization. Alternatively, young women were thought to be highly monitored and supervised by their guardians which was theorized to partially explain gender differences in victimization.

Routine Activates Theory

Analogous to Hindelang's (1976) lifestyle theory which focused upon places frequented, interaction with criminally prone individuals, and convenience

of target is Cohen et al.'s (1981) theory of routine activities. Cohen et al. (1981) expanded upon the lifestyle theory by proposing an opportunity-based theory of offending and victimization. Cohen et al.'s (1981) opportunity theory focused on descriptors of lifestyles probabilistically associated with increased risk of victimization. Their routine activities approach (Cohen and Felson 1979) primarily focused on a motivated offender, the availability of a suitable target, and the availability of a capable guardian (or lack thereof). Cohen and Felson, theorized higher risk of victimization resulted when a motivated offender converged with a suitable target absent a capable guardian (Cohen and Felson 1979). Cohen (1979) later summarized the routine activities model of offending to include an individual's everyday behavior/activities. Personal behavior/activities were theorized to bring about interactions between an individual and a potentially motivated offender. For instance, persons purchasing or selling narcotics were theorized as being more likely to converge with a motivated offender when compared with their non-drug using counterparts; thus, increasing the risk of victimization.

Cohen and Felson's (1979) routine activities theory has commonly been used to explain why and how males are at a heightened risk of victimization. With young unmarried males experiencing the highest rate of victimization; their routine and/or nocturnal activities with peer networks provide significant insight into the relationship between exposure and victimization. For instance, by being out at night, partaking in high-risk behaviors such as drug and alcohol use, participating in delinquent activities themselves, and frequenting high-risk areas, males are at an increased risk for coming into contact with a motivated offender without the protection of a suitable guardian (Lauritsen et al. 1991).

Delinquent Lifestyles Theory

Analogous to Cohen and Felson's (1980) routine activity theory is Jensen and Brownfield's theory of delinquent lifestyles (1986). Their theory of delinquent lifestyles proposed a positive relationship

between active offending and victimization. In this instance, active offending behavior was viewed as a causal mechanism with victimization resulting from “motives, vulnerability, or culpability of people involved in offending activities” (Jensen and Brownfield 1986). In other words, having a lifestyle of criminal behavior placed an individual in higher crime locations, high-risk situations, and interactions with other offenders, resulting in increased risk of victimization (Lauritsen et al. 1991). In 2007, Smith and Ecob reiterated Jensen and Brownfield’s theory of delinquent lifestyles (1986) by noting the interactive nature of the offender-victim relationship. Smith viewed victimization as “the outcome of an interactive process, in which both the eventual victim and the eventual delinquent played a part” (Smith and Ecob 2007).

Self-Control Theory

As previously alluded to in routine activities theory and delinquent lifestyles theory, there is a commonly noted relationship between an individual’s daily activities and risk of victimization. The General Theory of Crime (1990), along with lifestyle theories, has been used as a template for the explanation of victimization. Specifically, Gottfredson and Hirschi (1990) theorized an interactive relationship between low self-control and criminal outcomes. In their general theory of crime, low self-control was believed to develop during childhood as the result of ineffective parenting and inadequate socialization, thus producing later deviant outcomes. Moreover, low self-control was thought to affect behavior by manifesting itself through impulsive risk-seeking behaviors (Gottfredson and Hirschi 1990).

Ultimately, Gottfredson and Hirschi’s general theory of crime (Gottfredson and Hirschi 1990), proposed an inverse relationship between an individual’s level of self-control and behavioral outcomes. Empirically, low levels of self-control have consistently been linked with a person’s propensity to engage in criminal offending. As a result, scholars further proposed a correlation between low self-control and victimization (Pratt and Cullen 2000). Alternative to the substantive amount of research conducted on low self-control

and behavioral outcomes, research assessing the relationship between low self-control and victimization was not prominent until the 2000s.

In 1999, Schreck expanded Gottfredson and Hirschi’s general theory of crime by integrating it with lifestyle theories of offending. Specifically, Schreck (1999) sought to understand the underlying logic between the self-control-offending relationship and how an increased risk for offending was correlated with higher levels of victimization. Schreck’s concept of self-control and victimization focused on the idea that individuals primarily interact with persons similar to them. Specifically, Schreck purported an individual’s risk of victimization to be directly associated with the number of characteristics said individual shared with anti-social persons (Hindelang et al. 1978). Schreck further argued that victims, analogous to offenders, expressed lower levels of self-control resulting in more impulsive and risk-taking behaviors. Said behaviors were believed to increase offending, ultimately resulting in persons being perceived as more attractive and vulnerable targets (Schreck 1999).

Conclusion

The previously noted theories have been extensively supported by prior research. Offending behavior/lifestyles has been one of the most consistent predictors of victimization (Lauritsen and Laub 2007). Jensen and Brownfield (1986) classified offending behavior as a lifestyle or routine-based activity, suggesting an increased risk of victimization resulting from higher exposure to motivated offenders without the presence of a capable guardian (i.e., law enforcement). Specifically, Jensen and Brownfield (1986) found more serious deviant behaviors (i.e., drug and alcohol use) to act as desensitizing agents, ultimately making these individuals more attractive targets to motivated offenders.

Additionally, persons engaged in criminal activities were found to be more likely to use violence as a means of physical and reputational protection. This type of lifestyle activity increased the likelihood of succumbing to unintended consequences, ultimately increasing the potential risk of victimization (Stewart et al. 2008). Moreover, previous

research further discovered that offenders and victims shared many of the same behavioral and lifestyle characteristics as the result of them being the same person (Jensen and Brownfield 1986; Lauritsen et al. 1991).

Research regarding the offender-victim overlap has produced consistent findings across differing social contexts, cultures, and nationalities. Using data from the National Youth Survey, Lauritsen et al. (1991) further explored the relationship between offending and victimization by controlling for the “reciprocal influence of victimization of offending.” Lauritsen et al.’s (1991) findings provided significant support for the theory that offenders and victims do not simply share the same characteristics, but rather are the same person. Therefore, overall victimization among the male population has been substantively explained by male engagement in deviant, impulsive, high-risk lifestyles.

Synonyms

Brutality; Casualty; Injured party; Sadism; Savagery; Sufferer

Definition

A person harmed, injured, or killed as a result of another's behavior involving physical force intended to hurt, damage, or kill.

Introduction

Access to resources and mating opportunities determines the genetic fitness of an individual. Living in groups has meant that obtaining these resources is subject to the costs associated with competition and reciprocity, as well as resource acquisition. For these reasons, strategies that circumvent the need to compete or reciprocate by utilizing violence and intimidation to obtain resources and mating opportunities were selected for under some environmental conditions (Duntley 2015). Violence, like theft and other forms of social cheating, is a risky strategy but can minimize the costs involved in resource and mate acquisition. However, unlike cheating, violence not only confers resource and mating benefits but increases perceptions of physical dominance and social capital. In 2004, a massive 11% of deaths due to injury were the result of homicide and 3% resulted from war. Homicide (ranked fourth) and war (ranked ninth) both ranked in the top ten causes of death worldwide for 15–29 year olds. Further, males were almost three times as likely as females to die as a result of murder. However, females were more likely to suffer childhood sexual abuse (approx. 20% of all female children), intimate partner violence, and sexual violence (WHO 2010). Adaptations for violence between ancestral humans would have increased selection pressure for adaptations that assist an individual to avoid, defend against, and minimize the costs of, violence. The costs to the individual of becoming a victim of violence can vary from loss of resources, mating opportunities, and reputation, to complete loss of mate choice (Duntley and Shackelford 2012). These costs can continue to act on the individual's fitness for long periods of time, even decades. Further, individual differences in phenotype and behavior can increase the probability of becoming a victim of

violence. Evidence suggests that an individual's probability of being victimized can be increased by having been victimized previously (Finkelhor et al. 2007), as well as individual differences in personality (Coyne et al. 2000), and body language (Ritchie 2016).

This section will, however, focus on individual differences that offer avoidance, harm minimization, or protection from violence. The selection pressure placed on adaptations that minimize the costs associated with being a victim of violence is dependent upon the temporal context in which the adaptation is effective. For example, adaptations that increased the likelihood of avoiding violence completely would maximize genetic fitness relative to adaptations that minimized the costs of violence following the event (Duntley 2015). Due to this differentiation by temporal context, this chapter will consider evidence for adaptations to minimize the costs associated with being a victim of violence prior to, during, and following a violent event. Further, in order to locate these adaptations within a specific context, this entry uses the running example of adaptations to minimize the costs associated with rape. Rape is a unique example of intraspecific violence, as rape confers immediate reproductive advantages to the perpetrator while inflicting heavy costs to the victim's genetic fitness by removing the ability for mate choice while simultaneously lowering their mate value. Perhaps due to the heavy costs on the victim, evidence suggests that women have evolved specific adaptations to avoid and/or minimize the fitness costs of rape (McKibbin and Shackelford 2011).

Pre-Violence Adaptations

Adaptations that prevent the individual from becoming a victim of violence are the most effective harm minimization tools, and thus would be subjected to the most selection pressure. Included in this category are emotions, perceptions, behaviors, and social strategies. Emotions such as fear and anxiety act as a biological threat warning system that alerts the individual to signs of danger in the environment (Nesse and Marks 1994). The

triggering stimuli, intensity, duration, and valence of these emotions differ between individuals. Further, these factors determine whether the activation of fear and anxiety is a net benefit or cost to the organism. Too much fear and anxiety can reduce fitness by disabling the individual and preventing them from undertaking fitness-enhancing behaviors. Too little fear and anxiety places individuals at risk of attack from human and nonhuman predators. For this reason, fear and anxiety are regulated when the psychological systems of an individual are functioning optimally (Nesse and Marks 1994). When this system is not well regulated the psychology of that individual is often seen as disordered. Fear and anxiety that are of high intensity, present for long durations, and/or triggered by inappropriate stimuli is considered an anxiety disorder (Nesse and Marks 1994).

Fear and anxiety not only signal important information to the individual experiencing the emotion, but outward displays of these emotions (facial expressions, body language, and arousal) signal to those around us of the possibility of threat and a need for empathic concern (Aktar et al. 2013). Infants are known to respond to these outward signals when displayed by their parents/caregivers as young as 8 months of age (Boyer and Bergstrom 2011). This use of parental threat signals by infants is developmentally stable, manifesting in behavior at 8 months and lasting until 3 years of age in the form of stranger anxiety. Stranger anxiety is a fear response shown by infants when faced with unknown individuals, especially unknown men. When in the presence of strangers, the infant may cry, pull away, or hide. This behavior is thought to be an adaptive response to the threat of conspecific violence – violence which is more likely to be enacted by men who are strangers (Boyer and Bergstrom 2011). In an experimental test of the hypothesis, researchers demonstrated that infant anxiety, when confronted by a stranger, was higher when their parent expressed anxiety. Further, the parent's state anxiety response influenced infant stranger anxiety independent of a parental history of trait anxiety (Aktar et al. 2013). These early developmental fear objects drive infants and

young children to seek the safety of their caregivers, reducing their risk of becoming victims of violence (Boyer and Bergstrom 2011).

Fear and anxiety also play a role in motivating humans to form alliances and seek the safety of inclusion in a social group. Inclusion in a group can not only protect an individual from becoming a victim of violence, but also to minimize the costs associated with violent victimization through intervention during the violent attack, or in minimizing reputational costs by seeking retribution/revenge following an attack. A stressful environment motivates humans to seek social alliance through increases in prosocial behavior. Using an experimental design including a control group, researchers submitted the treatment group to a stress induction. Following this, all participants played decision paradigm games in order to measure their levels of prosocial behavior. Participants from the stress induction group showed significantly higher levels of trust, trustworthiness, and sharing than those in the control group (von Dawans et al. 2012). Prosocial emotions and personality traits have been found to increase integration in a group alliance, while antisocial personality traits and personality traits that promote a distrusting outlook, nervousness, and social anxiety have been found to decrease group integration and increase the probability of being victimized. Boele et al. (2017) found that in adolescents, being dissimilar from the group in levels of Machiavellianism (an antisocial personality trait) and neuroticism (a trait associated with jealousy, distrust, and social anxiety) led to an increased probability of being victimized. Being integrated within a group is an important protective factor against victimization, and environments that increase stress, fear, and anxiety motivate prosocial behaviors to help accomplish this.

Another strategy for minimizing the probability of becoming a victim of violence is the avoidance of high-risk environments. High-risk environments include unfamiliar territories, environments without easy access to escape routes, and places removed from allies. Females tend to place themselves in high-risk environments less than males. Differences in the rates of violence

committed against men rather than women can be partially explained by this difference in risk-taking behavior. In a sample of German students ($n = 275$), Fetschenhauer and Rohde (2002) found that men were more likely than women to be the victims of both violence and accidents, but that this relationship was mediated by men's increased levels of risk-taking and short-term orientation (a propensity to plan for short-term gain without consideration of long-term outcomes). After researchers controlled for risk-taking and short-term orientation, there were no differences in violent victimization rates between sexes. Risk-taking in males may confer fitness benefits in other ways, for instance, increasing resource acquisition and mating opportunities. However, in the context of conspecific violence, engaging in relatively low levels of risk-taking behavior and being oriented toward decisions with favorable long-term outcomes reduces an individual's probability of becoming a victim of violence. Further, the female propensity for avoiding the risks associated with environmental factors is enhanced during the fertile phase of the menstrual cycle, which is hypothesized to be an adaptation to avoid sexual violence (Bröder and Hohmann 2003).

Running Example: Pre-Violence Antirape Adaptations

Rape is a recurrent and unfortunate behavior that predominately affects women. The negative consequences of rape for women are numerous and substantial; as a result, it is likely that the problem of rape has resulted in selection pressure for physical and psychological antirape adaptations (McKibbin and Shackelford 2011). Adaptations that aid an individual in avoiding or reducing the probability of rape would confer the strongest fitness benefits. Previous research has suggested that a variety of adaptations aid women in minimizing the potential of becoming a victim of sexual violence. These include; changes in body language under stress (Fulham et al. 2017), increased caution during ovulation (Bröder and Hohmann 2003), and pair bonding

with dominant males (Wilson and Mesnick 1997).

Psychopaths and violent criminals have been found to be accurate assessing the vulnerability of women using cues taken from their body language and walking styles (Book et al. 2013). In fact, Ted Bundy notorious serial murderer and rapist said in an interview that he could "tell a victim by the way she walked down the street, the tilt of her head, the manner in which she carried herself, etc. . . ." (as cited in Holmes and Holmes 2010, p. 221). However, a counter adaptation exists for this ability to identify vulnerability through body language. In two studies (one between and one within subjects) using video footage of women walking Fulham et al. (2017) found that for women who had been victims of sexual violence the relationship between movement vulnerability cues and victimization history was moderated by hypervigilance. In other words, when women were hypervigilant people were unable to judge their history of victimization as accurately as when they were not hypervigilant. This shows evidence of adaptive behavioral consequences of the hypervigilance that is induced by exposure to dangerous situations.

Another set of hypothesized adaptations to avoid instances of rape center around the physiology of, and behavior associated with, fertile women's ovulatory cycle. Since the potential of fitness benefits for rapists is increased substantially when their victim is in the fertile phase of the menstrual cycle, it is reasonable to hypothesize that phenotypic variations that specifically guard against the potential of being attacked during ovulation would be selected for. Evidence exists of mechanisms of avoidance during the fertile period of women's reproductive cycles. Researchers from multiple studies have suggested that during ovulation women show increased levels of risk aversion compared to the remainder of the reproductive cycle (Bröder and Hohmann 2003). Bröder and Hohmann found that women self-reported having engaged in less high-risk activities if they were ovulating. Importantly, the effect of risk reduction at ovulation only occurred in women who were cycling normally. Women who were taking oral contraceptives that result

in a flattening of the natural hormonal cycle showed no change in risky behaviors. This research suggests a behavioral adaptation to reduce risk during the most vulnerable period of the reproductive cycle.

Other behaviors which are hypothesized to be selected for due to their antirape outcomes concern women's attraction to (or avoidance of) certain men. The Bodyguard Hypothesis makes the case that individuals co-residing with a male partner are less vulnerable to violent and sexual victimization. Further, although physically dominant men are less likely to make a long-term paternal investment, under some environmental conditions women would have a preference for pair bonding with more dominant men due to the protection they provide. Pair bonding with a physically dominant male not only affords protection through physical violence but also through reputational benefits. This is a trade-off between parental investment and protection and states that this trade-off is adaptive if calibrated with the dangers present in the environment. Wilson and Mesnick (1997) tested the Bodyguard Hypothesis by investigating Canada's homicide and violent crime data from a large-scale phone interview conducted in 1993. The resulting data were dichotomized with women either being classified as married (co-residing with a male sexual partner) or single and considered only attacks made by strangers. Data for non-lethal assaults included reported events of sexual violence which occurred in the 12 months prior to the survey. Data for lethal assaults was taken from Canadian homicide data for the period 1974–1992. Results showed that married women were significantly less likely than single women to be the victim of lethal or non-lethal sexual assault. For non-lethal sexual assault, an interaction was seen between prevalence and age at the time of the assault, with the gap in prevalence between married and single women largest in the 18–24-year-old bracket and consistently reducing until there was no difference between groups in the 65+–year-old bracket. For lethal sexual assault (femicide) a similar interaction was seen, however single women were most likely to be victims in the 25–34 age bracket (Wilson and Mesnick 1997). These results show

initial support for the Bodyguard Hypothesis and suggest that pair bonding does afford women some protection against violent sexual assault. However, further research is needed to investigate how these patterns differ according to the level of environmental risk in the associated environment as well as the effect of level of husband dominance.

Mid-Violence Adaptations

Some adaptations reduce the costs of violence to the victim while it is occurring. The defensive behaviors utilized by humans when encountering violence are similar to those used by animals. These may include defensive behaviors and postures, defensive attacks, verbal manipulations or attempts to de-escalate the situation, the summoning of allies to defend the victim, freezing, and fleeing from or escaping the attacker (Duntley and Shackelford 2012). In addition to these behavioral responses to violence, there are known physiological responses which include changes in heart rate, increased sweating on hands and feet, and increased startle reflex (Blanchard et al. 2001). Further, the context of the situation influences both the behavioral and physiological response to violence. When escape is possible the individual may make postural and physiological preparations to flee. Whereas when escape was unlikely, people prepare to freeze or fight.

Running Example: Mid-Violence Antirape Adaptations

Some hypothesized adaptations to reduce the costs of violence as it is occurring appear to be especially effective in the case of sexual violence. While males under threat of violence were disproportionately more likely to report that they would threaten attack, look for a weapon, or attack as a first choice response. Women were less likely to choose a defensive attack and more likely to scream or hide. This is especially true in contexts where fleeing was not a viable option (Blanchard et al. 2001). This may reflect the fact that when

faced with hypothetical scenarios both men and women report assuming that the attacker was male, thus making the size and strength differences between men and women a salient aspect of the decision. Further, men also noted that when choosing whether to attack their focus would be on the size/strength of the attacker (Blanchard et al. 2001).

Further research has shown that fear or death screams are an effective adaptation to reduce the costs associated with violence when fleeing or fighting is not an option. Death screams are long traveling and lasting, varying between high and low frequencies to maximize the chances of being located. These screams serve several adaptive purposes including warning others of the presence of a dangerous conspecific, seeking assistance from others (especially kin as their genetic fitness is directly impacted), briefly startling the aggressor, and even enticing other predatory actors to approach with the hope of acquiring low-cost resources (Hogstedt 2002). As mentioned earlier, females are more likely to report that screaming would be their first choice of defense against attack (Blanchard et al. 2001). However, much of the research on fear screams has been conducted on nonhuman animals. Further research is required in order to understand how this behavior manifests in humans.

Some evidence has also been reported showing antirape adaptations that increase defenses when the costs of being raped would be highest. As mentioned above, the fertile phase of a woman's menstrual cycle is a time in which rape can potentially result in pregnancy, increasing the costs of rape by subverting female mate choice. This is also the time at which the potential fitness benefits are highest for the attacker. Consequently, anti-rape adaptations that give protection specifically within the fertile phase of the menstrual cycle would be under increased selection pressure.

Post-Violence Adaptations

Post-violence adaptations work to decrease the fitness costs associated with having been violently victimized through behaviors that both reduce the

costs of the prior violence and decrease the probability of subsequent violence. Reducing fitness costs following violent victimization often involves behaviors designed to mitigate the problems associated with perceived vulnerability. Hypothesized post-violence adaptations include reputational fortification, behavioral changes, contextual (and sometimes continuous) hypervigilance, and seeking revenge.

Inflicting violence on another can be thought of as a welfare trade-off. Being the victim of violence imposes fitness costs on the victim and inclusive fitness costs through detriment to their kin. One way to minimize reputational costs and signal to competitors that any future violent victimization will come with a cost that is high relative to the benefits received, is to retaliate and/or seek revenge. McCullough et al. (2013) suggest that seeking revenge is a tactic of deterrence, and has evolved as an adaptive behavior to minimize the reputational costs imposed by violent victimization. Costs to reputation may reduce the mate value of the victim and their kin, but may also encourage further victimization from other individuals/groups. Victimization is a predictor of further victimization (McCullough et al. 2013). Retaliation may be sought by the victim or by their kin and social allies. The effectiveness of vengeance is affected by the length of time between the initial victimization, and the subsequent revenge. This is because the reputational damage inflicted by the initial victimization leaves the victim and kin with a reputation of exploitability, which both grows over the time that the violence has not been redressed and leaves a larger window for others to attempt to take advantage of this perceived exploitability.

Another hypothesized adaptation to reduce fitness costs after being the victim of violence is hypervigilance. Bisson et al. (2015) make a theoretical case for PTSD as a form of heightened defense following trauma. Fear and defensive behavior are a highly conserved adaptation in mammalian species. Selection for this is driven by predation, including intra-species predation. Behaviors associated with PTSD align well with anti-predation behaviors such as avoidance, attentive immobility, escape, aggressive defense,

appeasement, and tonic immobility resulting from hyperarousal, hypervigilance, and risk assessment, among other things. However, hypervigilance, hyperarousal, and anxiety act as defenses against possible harm and are adaptive only if calibrated to match the degree of threat in the environment. Too much anxiety can reduce fitness by disabling the individuals and preventing them from undertaking other fitness-enhancing behaviors. Too little anxiety and the individual is at increased risk from threats. Anxiety is regulated in order to balance this cost–benefit trade-off (Nesse and Marks 1994). Further, it is the subjective experience of the violence that dictates the level of the victim's hypervigilance.

Research showing the behavioral outcomes of PTSD symptoms, and their potential adaptive benefits, has been conducted. Mogg et al. (2007) found evidence of attentional biases in orienting gaze for fearful and angry faces, with high-anxious individuals more likely to orient to high-intensity fearful and angry faces than low-anxious individuals. Further research indicates that under low stress, high-anxiety individuals were biased toward attending to neutral faces over objects and attending to faces faster but for lower durations than controls. However, when stressed, high-anxiety individuals were avoidant of faces, again showing hypervigilance for the facial signals of others. Frankenhuys and Bijlstra (2018) used a low (university) and high (community) threat exposure sample to test for biased perceptions of facial emotion cues in crowd scenes. The community sample had higher exposure to violence as well as a more liberal threshold for identifying anger and sadness, showing a relationship between environmental threat levels and a bias toward over-perceiving the threat-identifying emotional signals. Combined, this research shows that individuals who have high levels of anxiety and/or sensitivity to being victimized are biased toward attending to and perceiving negative intent in the faces of others. This tendency would serve an adaptive function in an environment with a high probability of nefarious conspecifics.

Further perceptual and cognitive biases result from being subjected to violence and victimization that are specific to perceiving, interpreting,

and storing information about traumatic events. Lalande and Bonanno (2011) had participants' self-report events over a period of 4 years by responding weekly to a survey assessing whether events from a list of 50 options had occurred. At the end of the 4-year period, participants estimated how many times each of the 50 events had occurred. Participants generally underestimated the frequency of each event but gave more accurate responses for potentially traumatic events. Further, distress at the time of recall was related to the number of events recalled only for potentially distressing events. One of the most accurately remembered events was the experience of robbery or mugging.

Running Example: Post-Violence Antirape Adaptations

Examples of hypothesized adaptations that may be especially effective following violent sexual victimization include revenge and retaliation tactics, sex differences in the propensity for, and expression of, PTSD-like symptoms, and responses to forced impregnation. Seeking revenge against the perpetrator of sexual violence serves to decrease the reputational costs associated with being victimized. Further, retaliation signals a high cost-to-reward ratio to other potential sexual predators in the area and is used as a tactic of deterrence. This is especially important in the case of sexual violence as the costs to the victim not only include impacts on health and loss of resources but also a reduction in mate value, a loss of the genetic benefits of mate choice, and encouragement of further sexual victimization by conspecifics (McCullough et al. 2013).

Sex differences in the incidence and severity of PTSD-like symptoms following sexual violence can also be considered as an adaptive response to the increased selection pressure for antirape phenotypes. Women have a higher likelihood of developing PTSD-type symptoms and increased symptom severity following a violent attack. Bolstad and Zinbarg (1997) conducted a test of the uncontrollability/predictability model of PTSD, which states that symptom severity is

related to a perceived lack of control and/or triggering events that were beyond the control of the victim. Researchers considered self-reported child and adult sexual victimization, PTSD symptom severity, and locus of control in a sample ($n = 117$) of female undergraduates. Results show that increases in childhood sexualization are related to decreases in the locus of control. Further, low perception of control is related to high PTSD symptom severity following adult sexual victimization. Adult sexual victimization on multiple occasions or by force was related to higher PTSD symptom severity.

One possible explanation for the increased PTSD-like symptom incidence and severity in female victims of sexual violence is that rape is especially traumatic for women. This trauma is increased as a function of the woman's fertility (reproductive-age women experience higher trauma), marital status (married women experience higher trauma), and relationship to offender (trauma is highest if the rape perpetrator is a stranger), as each circumvents mate choice and/or reduces the genetic quality of offspring should the rape result in pregnancy (Thornhill and Thornhill 1990). When feeling unsafe in their environment, females self-impose significantly more restrictions on daily activities than males (Ávila et al. 2016). The trauma experienced as a result of rape acts as a psychological trigger to deter from entering, and/or increase hypervigilance to, the environment in which the trauma occurred.

Finally, adaptations have been hypothesized to directly reduce the fitness costs of a rape that results in pregnancy. Davis and Gallup (2006) make the argument that preeclampsia may have evolved as a strategy to terminate a pregnancy in the first trimester if there are biological signals (unfamiliar sperm) that the potential for paternal investment in the offspring is low. This strategy decreases maternal investment in offspring that have a low potential for genetic fitness, as in the case of rape pregnancies, where the woman's mate choice mechanisms have been circumvented. Davis and Gallup suggest that spontaneous abortion and postpartum depression may also result from a similar lack of paternal investment

signaling motivating a reduction in, or termination of, maternal investment.

Conclusion

The evolution of violent strategies for obtaining resources, reputations, and mating opportunities placed significant selection pressure on phenotypes that successfully avoid or reduce the costs associated with becoming a victim of violence. Adaptations to minimize the costs of violence decreased the benefit to the perpetrator, driving selection of more effective violent phenotypes. In this way, adaptations for inflicting, and avoiding/defending against violence evolved in an evolutionary arms race. Differential levels of selection pressure are placed on adaptations in response to violence, depending on the temporal context in which they are effective. This was made clear in this section by stepping through context-specific adaptations to minimize the costs of sexual violence.

Vigilance of Close Kin Versus Distant Kin

► Vigilance over Kin's Romantic Relationships

Vigilance over Kin's Romantic Relationships

Menelaos Apostolou
University of Nicosia, Nicosia, Cyprus

Synonyms

Conflict of mating; Kin interest in mating relationships; Vigilance of close kin Versus distant kin

Definition

The interest that parents and other family members demonstrate for an individual's romantic relationships.

Introduction

Individuals have a strong interest in the mate choices of other individuals with whom they are genetically related (Apostolou 2014b; Trivers 1974). As a consequence, mate choice usually

involves four parties: a woman and her family and a man and his family. This entry will examine the influence exercised by parents on their children's mate choices across different cultural settings.

In more detail, the entry will start by examining the reasons why parents have a strong interest in influencing their children's mating decisions. Subsequently, it will examine how such interest is manifested in preindustrial societies that base their subsistence on hunting and gathering and on agriculture and animal husbandry. Furthermore, it will examine how parental interest in influencing mate choice is manifested in modern post-industrial societies. It will also examine the implications of parental control over mate choice for sexual selection. Finally, the entry will conclude by proposing directions for future research in the area.

Why Parents Have an Interest in Their Children's Romantic Relationships?

The degree of genetic relatedness between parents and children is 0.5. That is, to say, on average, half of a parent's genes are inside its offspring and on average half of a child's genes come from its parent. As a consequence, the two parties have converging genetic interests: A parent cares about the 50 % of its genes that its child carries; a child cares about the 50 % of its genes that its parent carries. The degree of genetic relatedness indicates further that the two parties have diverging genetic interests. A parent cares also about the other 50 % of its genes that it does not share with its child; a child cares also about the other 50 % of its genes that it does not share with its parent (Trivers 1974). The diverging and converging genetic interests, mandated by the degree of genetic relatedness, result in a strong parental interest over their children's intimate relationships (Apostolou 2016b).

Diverging Genetic Interests and Parental Influence over Mating

Differences in genetic relatedness indicate that certain traits have differential fitness benefits in a

spouse and in an in-law. Genetic quality is a good example of such a trait: Some individuals carry more genetic mutations, while others have alleles that enable them to withstand better the challenges of the environment. Individuals are 0.50 related to their children and 0.25 related to their grandchildren, which means that it is more beneficial for them to get mates of superior genetic quality than in-laws of superior genetic quality: Individuals have more to lose if, due to poor genetic quality, their children rather than their grandchildren suffer survival or reproductive penalties, since they are more closely related to the former than to the latter (Apostolou 2014b).

Nevertheless, differential benefits are not a sufficient condition for disagreement to exist; for disagreement to exist, the choices one party makes need to inflict a cost to the other. If they do not, there would be no disagreement between the two. For instance, a mate of high genetic quality is beneficial to both parents and their children, albeit more beneficial to the latter than to the former. As both parties have to gain, no conflict should arise. Yet, conflict exists, the reason being that mate choice involves compromises, and the compromises that children are willing to make, in order to get traits they consider desirable, are not the ones their parents deem optimal.

More specifically, children are constrained by their own mate value with respect to the mate value of an individual they can attract (Li et al. 2002). That is to say, individuals looking for long-term mates cannot attract mates of much greater mate value than their own, because these mates would not be willing to enter in such a relationship, since it would not be optimal for them to accept mates of a mate value lower to their own (Apostolou 2014b; Buss 2003). Thus, mate choice inevitably involves compromises: In order to be able to attract and keep a long-term partner, mate seekers have to accept mates who score lower in desirable traits than they would ideally prefer.

The asymmetrical fitness benefits that certain traits provide result in mate seekers making compromises which are not to the best interest of their parents (Apostolou 2014b). For example, mate seekers would compromise on traits such as social

status and desirable family background in order to get a mate of good genetic quality. Nevertheless, because the latter trait is not as beneficial in an in-law, the accrued benefits will not balance the losses from the compromises in other desirable qualities. Therefore, from the parents' point of view, these compromises are not optimal. If they could exercise mate choice for their children, they would prefer a different mix of traits, a mix that would involve less of good genetic quality and more of other traits.

This argument is consistent with empirical findings: When children and their parents were given a budget of mate points in order to design a spouse and an in-law, respectively, children saved on traits such as good family background and similar religious background and spent what they saved in getting more of good looks (a proxy of genetic quality) and exciting personality (Apostolou 2014b). On the other hand, their parents saved on beauty and exciting personality and spent what they saved in getting more of good family background and similar religious background.

If parents and children had the same preferences, they would not make different compromises. For instance, if parents preferred good looks in an in-law equally to the degree their children prefer good looks in a spouse, they would end up making the same compromises. As a consequence, different evolutionary pressures are exercised on in-law and mate preferences, with the two diverging over traits which provide different fitness benefits to parents and children. Empirical research has, so far, identified that good looks and an exciting personality are preferred more in a spouse than in an in-law, while good family background and similar religious background are preferred more in an in-law than in a spouse (Apostolou 2014b, Apostolou 2015a; Buunk et al. 2008).

Overall, children are willing to engage in actions that benefit themselves but are costly to their parents such as getting good-looking mates, compromising on their social standing and family background. As a consequence, free mate choice involves an opportunity cost coming from diverging genetic interests, which is what parents

forgone when they allow their children to exercise mate choice freely on their own: Parents lose beneficial traits such as desirable family background, and their losses are not compensated by the gains in traits such as good looks, which are less valuable to them.

The opportunity cost of free mate choice results in selection pressure exercised on parents to place the mate choices of their children under their control: Parents who are predisposed to control mating have a selective advantage over those who do not, as the former are likely to have daughters and sons-in-law who maximize their inclusive fitness, while the latter are likely to have daughters and sons-in-law who maximize their children's inclusive fitness (Apostolou 2014b).

Converging Genetic Interests and Parental Influence over Mating

The degree of genetic relatedness between parents and children mandates that free mate choice involves a converging opportunity cost as well (Apostolou 2016b). If, for instance, their daughter mates with an aggressive and violent man who has low empathy, he may harm or kill her and her children, something that would be detrimental for the fitness of her parents who share their genes with her and her children. Or as viewed in another example, a young son, driven by his high libido, may attempt to form a sexual relationship with the wife of a high status and powerful man, which may lead to the latter killing him. This would impair considerably the fitness of his parents, who share half of their genes with him. Parents have certain qualities that enable them, if they are to interfere, to protect their children from making such erroneous choices.

To begin with, parents are older and more experienced than their children, which can enable them to distinguish better between potential mates, those who are dangerous for the welfare of their daughters and sons. Moreover, parents as opposed to their children do not base their decisions on libido and romantic love, which can cloud their judgment. In effect, parental intervention in mate choice can prevent children from

making erroneous decisions that may harm their own and their parents' fitness (Apostolou 2016b).

Apart from erroneous choices, children and especially daughters may fall prey to sexual assault and rape. Parents have qualities that enable them to protect their daughters from such danger: They are experienced, are physically strong, and have political connections. Thus, they can advise their daughters on how to avoid placing themselves in dangerous situations, provide physical protection, and ensure fierce retaliation if such an event occurs, which will act as a prevention measure that it does not occur in the first place.

Apart from erroneous choices and threats from others, children may also have issues that prevent them from effectively participating in the mating market. For instance, they may have a deformity, a health problem, and personality traits such as high introversion. Failure to find a partner affects negatively their reproductive success and consequently their own and their parents' fitness. Parents have qualities that can enable their children to address some of these issues.

To begin with, by being more experienced, parents can provide advice to their children on how to improve their performance in the mating market. Also, by having a wide and different social network than their children, they may use these social connections to help their children find appropriate mates. Last but not least, parents control resources, and they can divert some of these resources in compensating for the shortcomings of their children. For instance, in a preindustrial context, parents may be willing to pay a higher bridewealth or dowry in order to compensate for a handicap (e.g., a deformity) of their sons or daughters. In a postindustrial context, they may finance plastic surgery to address such a shortcoming, or they may choose to buy expensive cars or clothing to make their children more appealing in the mating market.

In sum, converging interests over mating, along with the capacity that parents have to improve the performance of their children in the mating market, give rise to a converging opportunity cost: If parents do not interfere in mate choice, they risk suffering fitness costs which arise from their children making erroneous mating

decisions and/or from failing to attract partners. The converging opportunity contributes further to the parental motive to control mate choice (Apostolou 2016b).

Overall, diverging and converging interests over mating give rise to an opportunity cost of free mate choice which motivates a strong parental interest over children's mate choices. This opportunity cost, and, thus, the strength of parental control over mating, is contingent on the sex of the in-law and the sex of the parent.

Contingencies in the Opportunity Cost of Free Mate Choice

Daughters Versus Sons

Women divert more parental investment to their children, and so they become the scarce reproductive resource to which men seek access (Trivers 1972). Accordingly, it is more beneficial for parents to control their daughters' than their sons' mate choices, as they can potentially extract more benefits from potential mates for them (Apostolou 2014b). Furthermore, a sexual adventure can commit a daughter's parental investment (i.e., pregnancy) to a man who is not necessarily beneficial for her. An unwanted pregnancy is not something that can be easily resolved, particularly in a preindustrial context. Also, a son can deny paternity, especially in a preindustrial context, where this is not something that can be easily proven. Moreover, due to parental uncertainty, men value chastity in a woman, as this preference reduces the risk of cuckoldry (Buss 2003).

For a similar reason, parents prefer a daughter-in-law who is chaste (Apostolou 2014b), a preference that reduces the risk of diverting resources in grandchildren which are not their own. Furthermore, due to menopause, the reproductive value of a daughter, following sexual maturity, decreases more rapidly with age than the reproductive value of a son. In effect, erroneous mate choices can have more detrimental consequences for the fitness of daughters than for the fitness of sons. In addition, because women constitute the scarce reproductive resource, they are the target of more intense mating effort, and, thus, they face a

higher risk of deception and assault by low-mate-quality men, who attempt to gain access to their reproductive capacity. Accordingly, the risk of erroneous mate choices is higher for daughters than for sons, which motivates parents to exercise more control over the mate choices of their daughters than the choices of their sons (Apostolou 2016b).

Moreover, women usually control less wealth than men (Whyte 1978), which means that daughters are more, and for a longer period, dependent on their parents' resources than sons. In addition, women are physically weaker than men that translates into daughters being more dependent on their family's protection than sons. Furthermore, because daughters are physically weaker than sons, parents can more readily employ physical force to inflict a cost on the former than on the latter. In effect, parents can control the mate choices of their daughters more easily than the mate choices of their sons.

Putting everything together, parents have a stronger incentive and a higher capacity to control the mate choices of their daughters than of their sons, which predicts that across societies, women will experience more parental control over their mating decisions than men.

Mothers Versus Fathers

The asymmetry in parental investment motivates men not only to compete between them, in being selected by women or by their parents (intersexual selection), but also to fight directly between them (intrasexual selection). The consequence of intrasexual selection forces is for men to be physically stronger than women, to tend to monopolize resources, to dominate the political scene and to have exclusive access to weaponry (Puts 2010). In effect, fathers and other male relatives control more resources than mothers and other female relatives, which in turn can be withheld if their children disobey them.

Moreover, the defense of the family unit rests on its male members, who are typically physically stronger, control weaponry, and have political connections. Consequently, children are more dependent on their fathers than on their mothers for protection. In addition, because fathers are

physically stronger than mothers, they have a higher capacity to use physical force on their children in order to align them with their will. Furthermore, because men have better access to political institutions (Apostolou 2014a), fathers can more readily employ them than mothers to inflict a cost to their children.

Also, due to menopause, women conclude their reproductive careers at an earlier age than men. This difference means that the residual reproductive value (i.e., the contribution to the population through future reproduction) is less for older women – to the point of being zero if they have passed the age of menopause – than it is for men of the same age (Apostolou 2014b). As a consequence, a mating deal such as an arranged marriage can be more beneficial for fathers, because it can provide them with resources that can be used for increasing their direct reproduction.

In addition, men have a higher reproductive variance than women, as they are not constrained by their biology in the number of children they can father. Men's reproductive success is positively related to the resources they control (Buss 2003), with men being able to deploy resources in such a way that enables them to practice polygyny and/or to attract multiple casual mates (Goode 1982). On the other hand, because women are constrained by their biology, conducting a polyandrous marriage and having multiple casual mates will not increase their reproductive output. Accordingly, a mating deal for their children, which would provide parents with resources, can potentially be more beneficial for a father than for a mother, as the former could use these resources to directly increase his reproductive success (Apostolou 2016b).

In sum, since fathers can inflict more cost to their children, and can convert more of the benefits they extract by controlling mate choice in reproductive success, they have more to lose if they allow their children to exercise mate choice freely. In turn, fathers have a stronger incentive than mothers to place their children's mating decisions under their control. In the following section, it will be examined how parental interest over mating is manifested across different society types.

Parental Influence over Mating Across Societies

Human societies can be classified in two main categories according to the level of technological development on which they base their subsistence, namely, preindustrial and postindustrial societies. Preindustrial societies can be further divided into the ones which base their subsistence on hunting and gathering and the ones which base their subsistence on agriculture and animal husbandry. Further divisions are possible, but for simplicity, the focus will be on the two aforementioned divisions.

Preindustrial Societies

Hunting and Gathering Societies

Starting from societies which base their subsistence on hunting and gathering, one study collected evidence from a sample of 190 contemporary foraging societies and analyzed their mating patterns (Apostolou 2014b). It was found that the most frequent mode of long-term mating, in approximately 70 % of cases, was arranged marriage, where parents choose spouses for their children. Similar findings were produced in a subsequent study which employed a smaller sample of societies from the Standard Cross-Cultural Sample (SCCS), which base their subsistence on hunting and gathering (Apostolou 2014b). It was found that, in approximately half of the foraging societies in the sample, marriages were arranged.

This study found also a considerable difference in the control that parents exercise on their daughters and their sons. In particular, for women, in approximately 53 % of the societies, marriage was arranged, and in approximately 8 %, it was based on free mate choice. For men, however, the percentages were 31 % and 40 %, respectively, indicating that men have a much larger space to exercise mate choice than women.

Both studies found that fathers and other male relatives exercise more control over their children's mate choices than mothers and other female relatives. In particular, in the study of 190 hunting and gathering societies, in about 44 % of the societies in the sample, fathers and

other male relatives arranged the marriages of their children with little input from mothers and other female relatives. In approximately 16 % of the societies, fathers dominated arrangements, but mothers had an important say; in approximately 34 % of the societies, both fathers and mothers had a roughly equal contribution; and in approximately 8 % of the societies, both parties contributed, but mothers dominated the arrangements (Apostolou 2014b). In the study based on the SCCS, it was found that in about 18 % fathers and other male relatives monopolized the marriage arrangements, in about 23.5 % both parties contributed but fathers had more say in arrangements, in about 47 % both parties had roughly an equal say, and in about 12 % both parties participated but mothers had more say (Apostolou 2014b).

Agropastoral Societies

The study which was based on the Standard Cross-Cultural Sample included a large number of societies which base their subsistence on agriculture and animal husbandry. Analysis of their mating patterns found that arranged marriage was the prevalent mode of long-term mating (Apostolou 2014b). More specifically, in societies which based their subsistence predominantly on agriculture, for women, arranged marriage was the most frequent mode of long-term mating in 40.3 % of the cases, followed by courtship subject to parental approval in 28.1 %, arranged marriage and free courtship marriage both practiced in 24.5 %, and courtship marriage in 7 % of the cases. For men, the respective frequencies were 30.4 %, 23.2 %, 23.2 %, and 23 %. In societies which base their subsistence predominantly on animal husbandry, for women, arranged marriage was practiced in 72.7 % of the societies, courtship subject to parental approval in 18.2 %, and both arranged marriage and courtship in 9.1 %, while there were no cases where marriage was based predominantly on courtship. For men, the respective ratings were 41.7 %, 25 %, and 16.7 %, while in 16.7 % of the cases, marriage was based on free courtship. In societies where subsistence was based on a combination of agriculture and animal husbandry, for women in

approximately 53 % of the cases, marriages were arranged, in 21 % were based either in arranged marriage or free choice, in 16 % on courtship subject to parental approval, and in approximately 10 % of the case were based on free mate choice, with the respective percentages for men being 39 %, 17 %, 11 %, and 33 %.

As opposed to ancestral hunting and gathering societies, several ancestral agropastoral societies left behind written records about their mating patterns. Accordingly, one study examined historical evidence and coded the mating patterns of 16 historical agropastoral societies (Apostolou 2014b). It was found that in 15 of them, marriages were arranged, and in one society in the sample, the historical sources were not clear about which was the dominant form of long-term mating.

Both studies also found that fathers and other male relatives are more influential than mothers and other female relatives over marriage arrangements. More specifically, in the study based on the SCCS (Apostolou 2014b), in societies which base their subsistence predominantly on agriculture, in 25 % of the cases, males monopolized marriage arrangements; in approximately 39 % of the cases, both parents participated but men had more say; in 22 % fathers and mothers had an equal say; and in 14 % both parents participated but mothers have more say. In societies which base their subsistence on animal husbandry, in 71 % of the cases, both parents participated in marriage arrangements, but fathers had more say, and in 29 % of the cases, both participated with roughly equal say. Finally, in societies which subsistence is based on both agriculture and animal husbandry, in 80 % of the case, both parents participated but men had more say, in 10 % men dominated marriage arrangements, and in 10 % both parents had an equal say.

In the study of 16 historical agropastoral societies, there was information about sex differences in parental control over mating for 14 societies (Apostolou 2014b). In ten societies, marriages were predominantly controlled by fathers, while in four societies, both parents participated but fathers had more say. Furthermore, there was no case reported where women had more say or where they dominated marriage arrangements.

Agropastoral Versus Hunting and Gathering Societies

Agropastoral societies are more technologically advanced than hunting and gathering ones, and consequently, they produce more material wealth. Accordingly, individuals in the former are likely to have more wealth at their disposal than individuals in the latter. For instance, individuals in agropastoral societies are likely to own land, animals, food surpluses, and money. On the other hand, individuals in hunting and gathering societies are likely to own some artifacts, weapons, and household objects. As a consequence, parents can gain more resources from controlling mate choice in agropastoral than in foraging societies.

In the same vein, parents are likely to control more wealth in agropastoral than in foraging societies, which means that children have more to lose if they disobey their parents in the former than in the latter societies. Furthermore, in hunting and gathering societies, individuals can rely on their own hunting or gathering effort in order to sustain themselves. In agropastoral societies, on the other hand, they need to rely predominantly on the cultivation of land or the herding of animals, which are owned by their parents. In effect, individuals are more dependent on their parents' resources in the former than in the latter societies. Parents can then use this dependence in order to impose their will. Overall, parents have more to gain by controlling mate choice, and they can more easily do so in agropastoral than in foraging societies, predicting a stronger control over mating in the former than in the latter (Apostolou 2016b).

Due to intersexual competition, men usually monopolize resources (Buss 2003); therefore, when more resources are available, men have control over more of them. Accordingly, in agropastoral societies, which produce more wealth, children have more to lose if they disobey their fathers than their mothers. In addition, more resources increase the incentive of others to monopolize them, which means that there is a higher need to defend the family unit and its members. Thus, children are more dependent on their male parents' protection in agropastoral than in foraging societies.

The higher amount of produced resources results also in greater emphasis to be placed on military preparation, which is the realm of men (Apostolou 2014b). As a consequence, more sophisticated and lethal weapons are produced, to make defense of resources more effective and/or to get more effectively the resources of other groups. To these weapons, men usually have an exclusive access, which amplifies their ability to impose their will by force on their children. Overall, fathers have a greater capacity to inflict a cost to their children in order to align them with their will in agropastoral than in foraging societies, which predicts that male parental control over mating will be stronger in agropastoral than in foraging societies.

Consistent with this prediction, the study which was based on the standard cross-cultural sample compared the patterns of mating between societies which base their subsistence on hunting and gathering and between the ones which base their subsistence on agriculture and animal husbandry (Apostolou 2014b). The results indicated that arranged marriage was more dominant in agropastoral than in foraging societies. Last but not least, in agricultural and pastoral societies, male parents and relatives had more decision-making power over marriage arrangements than female ones. Actually, there was not even a single case reported where female relatives dominated marriage arrangements.

Postindustrial Societies

In postindustrial societies, parents cannot control their children's mating decisions directly, and they do so indirectly through manipulation (Apostolou 2014b). In particular, Sussman (1953, p.80) reported that parents employ means such as "cajolery, persuasion, appeals to loyalty, and threats" in order to influence their children's mating behavior. Another study found that modern Chinese parents in the USA attempt to create environments, such as staging a barbecue, in which their children can meet other individuals of Chinese descent and, therefore, of desirable background (Ikels 1985). A more comprehensive study of manipulation identified 12 tactics that parents employ on their children and 4 tactics

that they employ on their children's mates (Apostolou 2014b).

In more detail, when parents find their daughters and sons engaging in undesirable relationships, they attempt to break these relationships either by manipulating their children and/or by manipulating their children's mates in terminating the relationship. For example, in the former case, they advise their children against the relationship, they attempt to bribe them to dissolve the relationship, or they try to match them with different mates. In the latter case, they threaten their children's mates, they are rude to them, or they try to find out things to use against them (Apostolou 2014b). Parental manipulation can cause strain upon their children's relationship, effectively undermining it. For instance, one study found that such kind of manipulation can indeed be effective in weakening an undesirable relationship (Apostolou et al. 2015).

There is evidence that suggests that in a post-industrial context, parents are more concerned about the mating decision of their daughters than of their sons. In a Greek-Cypriot sample, one study examined the willingness of parents to apply 12 tactics of mate choice manipulation separately on their daughters and sons (Apostolou and Papageorgi 2014). It was found that parents were more willing to apply manipulation for the purpose of influencing mate choice on their daughters than on their sons.

Preindustrial Versus Postindustrial Societies

Postindustrial societies are more technologically advanced than preindustrial ones. Technological orientation demands a long period of training before one is able to participate effectively in the labor market; thus, in postindustrial societies, children are married at a later age when they are financially independent from their parents. In addition, the presence of social protection systems, such as the police, results into children being less dependent on their families for physical protection. In preindustrial societies, however, children are married relatively young, since a long period of education or training is not required and they are, therefore, more dependent on the resources of their parents (Apostolou 2014b).

Also, as the social protection systems are not well developed or inexistent, children have to rely on their parents for physical protection. Accordingly, children are much more dependent on their parents' resources in preindustrial than in postindustrial societies.

In postindustrial societies, individual rights are well protected, and parents are prevented by the rule of law to use physical force on their children. But even if they were allowed to do so, this course of action would not be easy, since children are getting married at an older age when they are usually physically stronger than their parents. On the other hand, in preindustrial societies children are married younger, which means that their parents are also younger and thus better able to use physical force on them. In sum, the capacity of parents to employ physical force on their children to align them with their will is larger in pre-industrial societies than in postindustrial ones. Overall, parents in preindustrial societies can control their children's mate choice more easily than parents in postindustrial societies (Apostolou 2016b).

Furthermore, children in postindustrial societies are married at an older age than children in preindustrial ones, which means that their parents are also older and have a lower reproductive capacity. Therefore, any potential gain from control over mating has a limited potential to be converted into additional offspring in post-industrial than in preindustrial societies. This capacity is further reduced by the fact that polygyny is not allowed in the vast majority of post-industrial societies. This is not the case, however, for preindustrial societies where polygyny is usually allowed and children are married young and have relatively young parents who can convert benefits from a marriage deal into additional children.

Also, in postindustrial societies, children are married at a later age so they are more experienced, which means that they can make fewer erroneous mate choices. Also, the widespread use of contraceptives and the after-day pill, along with the effective treatment of most sexually transmitted diseases, turns erroneous mate choices in postindustrial societies less

consequential, reducing in effect the interest of parents to control their children in order to protect them. Overall, it is predicted that parental control over mating is stronger in preindustrial societies than in postindustrial ones.

Moreover, in preindustrial societies, wealth is predominantly controlled by the male members of a society, while in postindustrial societies, it is more equally distributed across the sexes (Apostolou 2014b). In addition, men in preindustrial societies are less constrained in employing their physical strength in controlling their children. Also, fathers can benefit more by a marriage arrangement in a preindustrial context, as the extracted wealth goes under their control. In addition, preindustrial societies are more aggressive than postindustrial ones, and given that war and protection are predominantly the domains of men (Puts 2010), children are more dependent on their male parents' protection in preindustrial than in postindustrial societies.

As discussed above, in preindustrial societies, as opposed to postindustrial ones, polygyny is permitted, and parents are relative young when their children get married. Nevertheless, these differences favor predominantly men who have a higher residual reproductive value and a higher reproductive variance than women. Overall, male parents have more to gain by controlling their children's mate choices, and they can more easily do so, in preindustrial than in postindustrial societies, which predicts that male parental influence will be higher in the former than in the latter.

Consistent with this prediction, in all postindustrial societies, marriage is typically based on free choice, but parents exercise an influence on their children's mate choices, primarily through manipulation (Apostolou 2014b). In addition, although in preindustrial societies fathers dominate parental control over mating, this pattern reverses in postindustrial societies.

More specifically, one study asked a sample of Greek-Cypriot parents to indicate their willingness to influence their children's mate choices (Apostolou 2014b). Mothers reported a significantly higher willingness to do so than fathers. In addition, participants were also asked to indicate whether their parents had or have been

attempting to influence their mate choices. Participants reported that their mothers had or have been attempting to influence their mate choices more than their fathers. Finally, in the studies of manipulation discussed above, it was found that mothers were more willing to employ manipulation in order to influence their children's mate choices than fathers (Apostolou 2014b; Apostolou and Papageorgi 2014).

One reason behind this reversal is that fathers in postindustrial societies have not much to gain from influencing their children's mate choices, which weakens their motivation to do so. On the other hand, due to paternal uncertainty, if children make erroneous choices that reduce their fitness, mothers have potentially more to lose because they are more certain that their children are actually their own. As a consequence, mothers have a stronger incentive than fathers to influence their children's mate choices, in order to protect them from making erroneous mate choices. This difference is present in preindustrial societies, but it is masked by the stronger interest of fathers to control mate choice in order to benefit themselves. In postindustrial societies, where this interest resides, mothers' interest to influence mate choice becomes more apparent.

Parental Control over Mating Across Time

The genus *Homo* appeared on earth approximately two million years ago, and for most of this period, our ancestors lived in small bands of hunters and gatherers; thus, most of human evolution took place in this context (Tooby and Cosmides 1990). About 10,000 years ago, the agropastoral revolution took place, and most of our ancestors shifted to a non-nomadic life and a mode of subsistence based on agriculture and the herding of animals (Price 2000). Human societies were to be transformed again following the Industrial Revolution, which began in the eighteenth century Britain and has led to the modern way of life.

On the basis of the evidence on the mating patterns across different society types discussed above, specific predictions can be made about the prevailing patterns of mating at each stage of human evolution. Starting with the former and

the longest one where our ancestors lived as hunters and gathers, it is predicted that parents would have been influential over their children's mate choices. Direct information on ancestral hunter and gatherer mating patterns is lacking, as these societies did not leave behind any written records pertaining to the first and the longer period of human evolution. Nevertheless, there is a good source of information, namely, contemporary hunters and gatherers whose mating patterns have been studied by anthropologists. The mating patterns typically found in these societies are likely to be characteristic of the hunter-gatherer way of life and, consequently, are likely to be similar to those in ancestral hunter-gatherer societies (Apostolou 2014b).

Anthropological evidence indicates that in ancestral foraging societies, mate choice would be regulated, with parents exercising considerable influence over their children's mate choices (see above). Phylogenetic analysis, which attempts to reconstruct the conditions prevailing in ancestral societies, has provided additional evidence that the patterns of mating found across contemporary hunters and gatherers (e.g., arranged marriage) were also prevalent in ancestral ones (Walker et al. 2011).

About 10,000 years ago, a different period of human evolution begun as our ancestors started shifting from a mode of subsistence based on hunting and gathering to a mode of subsistence based on agriculture and the herding of animals (Price 2000). As historical evidence is lacking about ancestral foraging societies, comparisons between ancestral foraging and ancestral agropastoral societies cannot be made. Comparisons between contemporary hunting and gathering societies and agropastoral societies can be made, however, that can be revealing about the effects of the ancestral transition. One study that made such comparisons found that in agropastoral societies, parental influence, mainly male parental influence, is stronger than in foraging societies and male children experience considerable losses to their freedom to exercise mate choice (Apostolou 2014b). This finding is also consistent with evidence from historical agropastoral societies, where male parental control over mating

dominates and where both male and female offspring have a very limited space to exercise mate choice freely (Apostolou 2014b). Accordingly, it can be concluded that the agropastoral revolution resulted in the strengthening of parental control over mating and the limiting of the space that individuals had to exercise mate choice.

Furthermore, comparisons between pre-industrial and postindustrial societies indicate that the transition to industrialism, which started about three hundred years ago, brought gradually a weakening in parental control over mating and an increasing freedom to individuals to exercise mate choice. It also brought a weakening in fathers' interest to influence their children's mate choices.

In sum, on the basis of the available evidence, the following conclusions can be reached: During the earliest and longer period of human evolution, where our ancestors lived as hunters and gatherers, parents had been influential over their children's mate choices. The transition to a mode of subsistence based on agropastoralism increased considerably the strength of this influence, while the transition to industrialism in the eighteenth century has resulted in a sharp decline in this influence.

Sexual Selection and Parental Control over Mating

When parents succeed in controlling their children's mating decisions, they become a significant sexual selection force: Traits which make an individual more likely to be chosen by parents as a daughter- or son-in-law are selected and increase in frequency in the population (Apostolou 2014b, 2016b). The anthropological and historical records indicate that during most of the human evolutionary time, parents had been successful in doing so. In turn, this leads to the conclusion that parental choice has been an important sexual selection force, driving sexual selection in the human species (Apostolou 2014b).

This conclusion runs against the assumption made by several evolutionary scholars that sexual selection in our species has been driven by

individual mate choice and in particular by female choice (Miller 2000). There is a combination of factors that led to the wide adoption of this assumption, including the evolutionary theory on parental investment, evidence from nonhuman animal studies, and the patterns of mating prevailing in modern postindustrial societies.

Starting from the former, the asymmetry in parental investment, with females diverting more to their offspring than males, turns the former to become the scarce reproductive resource to which the latter seek reproductive access (Trivers 1972). The asymmetry in parental investment leads to the prediction that there will be an asymmetry in mating effort, with males seeking access to females and females choosing to which males they will grant this access. In turn, this asymmetry causes another asymmetry, namely, stronger sexual selection pressure exercised on males than on females: Since females choose and males are chosen, males are under stronger selection pressure than female to evolve traits that will make them more likely to be chosen as mates. In consequence, sexual selection is driven by female choice.

This model of sexual selection seems to fit well the patterns of mating in several nonhuman animals (Andersson 1994). The classic example is peacocks' tails: Strong female choice has led to the evolution of large and elaborated tails, which serve the purpose of making peacocks more appealing to peahens (Zahavi and Zahavi 1997). This model appears to fit well also the patterns of mating observed in modern postindustrial societies, where men exercise considerable mating effort, engaging in a variety of behaviors in order to appeal to women, ranging from risk taking to buying expensive cars (Buss 2003; Miller 2000).

This model is, however, inconsistent with the patterns of mating observed in modern and ancestral preindustrial societies: Women do not choose mates, but their parents do so for them. It follows that it is unlikely for female choice to be the primary sexual selection force driving sexual selection, with parental choice being a better candidate: Diverging and converging interests over mating motivate parents to control their children's

mating decisions (Apostolou 2016b). The asymmetry in parental investment makes it more profitable for parents to control the mate choices of their daughters than of their sons (Apostolou 2014b). It is also more fitness increasing for male parents than female parents to control mate choice. Accordingly, men choose other men as spouses for their daughters, which appears to be the most common pattern of mating across preindustrial societies (Apostolou 2014b). Accordingly, during most of the period of human evolution, sexual selection has been driven predominantly by male parental choice.

Although it is difficult to change the established way of thinking, an endeavor that becomes even more difficult if one considers that most research takes place in a postindustrial context where individuals are relatively free to choose their mates, doing so is necessary in order to understand the selection forces that have shaped traits involved in mating.

Areas of Future Research

Although it has been known to anthropologists for several decades now that in preindustrial societies parents and other family members exercise considerable influence over their children's mate choices, theoretical and empirical evolutionary work in this domain has only been recently initiated. Accordingly, this section proposes directions for future research, which can be fruitful in enabling us to understand kin's influence over mating, and its evolutionary implications.

Evidence from historical studies indicates that the transition from a context where mate choice was regulated to a context where it is not has occurred very recently for selection forces to have managed to adjust traits involved in mate choice to modern conditions. As a consequence, several traits may not be able to meet the demands of a modern context where mate choice is not regulated, resulting in individuals who have them to experience poor mating performance (Apostolou 2015b). It has been argued that such traits include mechanisms that regulate sexuality, specific personality traits, mechanisms which

regulate attention to looks, mechanisms which regulate mating effort, and flirting skills (Apostolou 2015b, c, 2016a, e; see also 2016c). Future research needs to examine empirically whether there is variation in these mechanisms that is not optimal for a free mate choice context and to which degree this variation impairs the formation of intimate relationships. Future research need to attempt also to identify other factors which exhibit a nonoptimal variation and to examine possible interactions between the different factors in affecting performance in the mating domain.

All research efforts so far have focused on the influence that parents exercise over their children's mate choices. However, the degree of genetic relatedness indicates that genetic relatives other than parents would also have a strong interest in an individual's mating decisions, and consequently they would be motivated to exercise some influence over it. For instance, it would be harmful for a brother's fitness if his sister marries an individual who scores very low in kindness, as he can physically harm her, decreasing in effect his fitness as he is genetically related to her. Thus, it would pay for him to interfere in her mate choices, prompting her, for instance, to stay in a relationship with a man who is kind and to terminate a relationship with a man who is not. Future research needs to study in detail the influence that genetic relatives other than parents, including grandparents, siblings, uncles, aunts, and cousins, exercise on an individual's mating decisions.

Furthermore, in postindustrial societies, parents exercise indirect influence over their children's mating decisions, predominantly through the use of manipulation. Several tactics of manipulation that parents use for this purpose have been identified (Apostolou 2014b; Apostolou and Papageorgi 2014). Nevertheless, these tactics have only been studied in one culture (i.e., the Republic of Cyprus), and future studies need to examine the manipulation tactics that parents employ in different postindustrial cultures. Additional empirical work that would examine how effective these tactics are in aligning children's mate choices with the preferences of their parents is also required.

Future theoretical and empirical research can benefit by adopting an evolutionary perspective, where parental choice rather than female choice had been dominant during human evolutionary time, in understanding other phenomena which relate to sexual behavior. For example, rape has been interpreted as a strategy that has evolved to enable low-mate-quality men to bypass female choice (Thornhill and Palmer 2000). Nevertheless, since women in the preindustrial context are predominantly controlled by their parents, this argument needs to be revised: If rape is indeed an evolved strategy, it has evolved to bypass predominantly parental choice and not female choice (Apostolou 2014b). Furthermore, the presence of this strategy in ancestral times would have exercised pressure on parents to evolve strategies that would enable them to protect their daughters. In turn, such strategies would weaken selection pressures on women to evolve rape-protection strategies, as they receive the required protection from their parents. In a postindustrial context, where parents are out of the picture, women may be relatively unprotected and vulnerable to rape (Apostolou 2014b). Future research needs to examine the consequences for women lacking their parents' protection in increasing their vulnerability to rape and sexual assault.

Same-sex attractions remain currently one of the toughest challenges for evolutionary scholars to explain: Given the evolutionary importance of reproduction, any predispositions for same-sex attraction would be eliminated by selection forces. However, same-sex attractions are found in relatively high prevalence in the population, especially in women (LeVay 2010). Such a high prevalence is less enigmatic if one considers that human sexuality has been shaped in a context where mate choice was regulated: Individuals who experience same-sex attractions would get opposite-sex spouses from their parents, and they would have children with them, passing their dispositions to future generations. Thus, such dispositions would be maintained in the population, because they have a limited negative fitness effects (Apostolou 2016d). Future research needs to investigate further the implications of parental control over mating in understanding the evolution of same-sex attractions.

Conclusion

To conclude, this entry has demonstrated that across human societies, parents exercise strong control over their children's mate choices. In preindustrial societies, the influence is direct, and it is manifested in arranged marriage, where parents choose spouses for their children, while in postindustrial societies, the influence is indirect, and it is manifested predominantly through manipulation. It was also argued that there are good reasons to believe that parents had been exercising strong control over mating during most of the period of human evolution. This being the case, sexual selection has been driven predominantly by parental choice. Parental control over mating has received little attention from evolutionary-minded scholars, and as a consequence, there is considerable opportunity for future research in this area.

Vigilance, Sentinels, and Alarms

Fernando A. Campos

Synonyms

Antipredator behavior

Definition

Vigilance is attentive behavior directed at an animal's surroundings to detect or monitor perceived dangers. Sentinels are individuals in a social group that scan the surroundings while groupmates are engaged in other activities nearby. Alarm calls are vocalizations given by animals in response to perceived danger from predators.

Introduction

Predation is a fundamentally important selective pressure.

Given the large fitness costs of failing to detect and avoid predators, there should be strong selective pressure for behaviors that enable the early detection of possible threats.

Vigilance

Vigilance involves scanning the environment for possible dangers. Despite its clear individual

benefits, vigilance may have significant opportunity costs in the form of time taken away from other important activities, such as foraging, mating, and socializing. Accordingly, vigilance may have chronic effects on individual fitness. Thus, if predation risk varies over time or space, then animals would benefit from adjusting vigilance to levels of predation risk – that is, they should be more vigilant in high-risk environments and less vigilant in low-risk environments (Lima and Dill 1990). The benefits of improved early predator detection through the collective vigilance of multiple animals are often considered to have central importance in the evolution of sociality. Numerous studies of group-living animals have demonstrated a group-size effect on vigilance, in which animals in larger groups reduce vigilance levels and instead allocate more time to other activities such as feeding and resting (Roberts 1996). Two well-supported explanations for the group size effect on vigilance include the “many eyes hypothesis,” whereby overall predator detection probability increases in larger groups because there are more eyes scanning for predators; and the “dilution effect hypothesis,” whereby individual risk of mortality during a predator attack decreases in larger groups because there are more individuals present. Some animals, notably many species of nonhuman primates, do not show a consistent group size effect on vigilance, perhaps because much vigilance in primate groups is directed within the group to monitor the risk of competition with groupmates, which may increase as group size increases (Treves 2000).

Sentinels

An interesting variation on the benefits of social vigilance can be seen in species with sentinel systems, in which multiple individuals coordinate their vigilance such that one or more individuals stand guard, often from a vantage point, and scan the surroundings while nearby groupmates are engaged in other activities such as foraging. Sentinel behavior has been described in a variety of birds and mammals (Bednekoff 2015). A key question about the evolution of sentinel behavior

is whether sentinels are safer than nonsentinels because of their vigilance, or if sentinels are at greater risk because they are more likely to be targeted by predators due to their relatively exposed positions. This question is crucial for clarifying whether sentinel behavior can be viewed as a fundamentally “selfish” behavior, or if cooperation (e.g., kin selection or reciprocal altruism) is necessary to explain its evolution (Clutton-Brock et al. 1999).

Alarms

Many prey animals produce specific alarm vocalizations when they detect a predator. The ultimate function of alarm calling – that is, the nature of the fitness benefits to the caller – has been a topic of considerable debate in behavioral ecology. One prevalent view is that alarm calls function primarily to alert others to danger (Smith 1965). In this view, alarm calls are altruistic insofar as they benefit others but potentially put the vocalizing animal at greater risk by drawing the predator’s attention (Sherman 1977). Kin selection may explain the evolution of altruistic alarm calling if the inclusive fitness benefits that accrue to the caller by alerting kin to danger exceed the direct cost of giving the alarm call. An alternative hypothesis is that alarm calls function primarily to signal to predators that they have been detected, thereby discouraging them from attacking (Smythe 1970). In this view, alarm calls provide direct fitness benefits to the vocalizing animal. Landmark research on vervet monkeys (*Chlorocebus pygerythrus*) revealed that vervet alarm calls given to different predators are acoustically distinct and that receivers appear to discern this information from the calls alone by exhibiting appropriate evasive responses to experimentally broadcast calls (i.e., “playbacks”) in the absence of an actual predator (Seyfarth et al. 1980). Subsequent research has demonstrated that alarm calls in a variety of animal taxa can encode information about predator type and the degree of risk. Signals that communicate such

information in a manner analogous to basic words have been termed “functionally referential” (Marler et al. 1992).

Violation of Long-Term Mate Preferences

M. L. W. Long¹ and Norman P. Li²

Synonyms

Deception; Intersexual strategic interference; Long-term mating; Mate preferences; Mate selection

Definition

Violations of long-term mate preferences refer to instances in which a person in a long-term relationship has mate preferences that were in place when the relationship commenced but subsequently are not being met.

Introduction

According to an evolutionary perspective, mate preferences evolved through natural and sexual selection to adaptively guide individuals to select reproductively viable mates (Buss and Schmitt 1993; Symons 1979). A host of evidence has supported various hypotheses on mate preferences, including studies conducted through surveys, numerous naturalistic settings, and modern, live-interactive contexts (Li and Meltzer 2015). Although mate preferences have, on average, led to adaptive choices over thousands of generations, they are not always fulfilled in the mates that people actually select, and even when they initially are, conditions occur that eventually prevent at least some preferences from being met. Indeed, selecting mates and maintaining them over the course of a long-term relationship involves a large degree of judgment uncertainty and

dynamics between individuals whose reproductive interests are overlapping but far from identical. Initial assessments can be inaccurate, conditions can change, and partners often face sexual conflict; hence, there is plenty of room for mate preference violations to occur. Here, the focus is on violations of long-term mate preferences – ways in which one's preferences for a long-term, committed relationship partner are not being met during such a relationship.

Long-Term Relationships

Long-term relationships involve commitment over a relatively long time horizon and include steady relationships and marriage. From an evolutionary perspective, long-term mating is adaptive for many reasons including that it allows partners to jointly pool resources and efforts in cooperatively raising offspring (Buss and Schmitt 1993). Although mate preferences likely evolved to adaptively guide the selection of reproductively beneficial mates, there are several reasons that mate preference violations may occur in a long-term relationship, including the following: (1) inaccurate assessment of traits during the courtship phase, (2) a relative decline in a partner's mate value, and (3) conflicting strategic interests. Generally, lower consistencies between ideal mate preferences and associated perceptions of one's partner result in lower levels of relationship satisfaction. However, the consequences of long-term mate preference violation also vary depending on factors such as an individual's own mate value and whether there are alternative candidates who are more attractive than one's existing partner.

Inaccurate Initial Assessment of Traits

During the mate selection process, individuals assess one another and try to obtain mates who are in line with their evolved mate preferences. Preferences have been characterized by evolutionary psychologists using various models, including

those where individuals utilize minimum-criteria trait thresholds as well as priorities to ensure reproductive viability. However, the precise value of each trait may be hard to observe. Indeed, this is a potential reason why many speed-dating studies have failed to find correspondence between people's mate preferences and the criteria that they use to select actual mates (Li and Meltzer 2015). More generally, trait and other mating-relevant information is likely imperfect not only in the first few minutes of initial meetings such as in modern speed-dating events, but even over time. A potential barrier to accurate assessment is that traits are often misrepresented by individuals being assessed. For example, especially during mate selection, people may present themselves as favorably as possible and not disclose negative aspects about themselves; women may attempt to appear younger – and hence, more fertile – than they really are; and men may attempt to represent higher-than-actual social status and resources (Tooke and Camire 1991). In the modern day, the multi-billion dollar cosmetics industry and rapidly expanding plastic surgery market attest to the prevalence of women appearing younger and more reproductively fit. Likewise, expensive sports cars are often purchased by men who incur large amounts of debt and hence, cannot actually afford (over the long haul) such expensive indicators of status. Indeed, in a competitive mate-market context, the strategic use of misrepresentation may have been selected for because successful deception can promote one's own reproductive fitness (Tooke and Camire 1991).

Relative Decline in Partner's Mate Value

Another way that preferences can be violated within an ongoing long-term relationship is when, over the course of a relationship, one partner loses or gains mate value relative to the other person. Because mate preferences or standards tend to be indexed to people's own desirability in the mating market (e.g., more physically attractive women desire men with more resources), changes in relative mate value will tend to violate the mate

preferences of the person whose mate value becomes relatively higher. For example, a man may lose his job, which decreases his social status and mate value and thus, his partner's preference for high social status may be violated. Indeed, women are especially likely to leave a marriage when the husband loses his job. Similarly, for women more than men, a decrease in mate value could occur due to beauty (and fertility) fading with age, which may violate partners' preference for a physically attractive and fertile mate. Noticeable changes in health can also directly impact both men's and women's mate value. A change in the operational sex ratio could also trigger relative changes in mate value, in that the sex that is decreasingly represented in the population gains position and leverage (by having more potential mates competing for them) over the sex with whose numbers have increased.

Conflicting Strategic Interests

People in long-term relationships may also have their preferences violated from conflicts in mating strategy. For instance, it may be in the interest of one person to have backup mates or affair partners but to have one's partner remain faithful and removed from mating options. Men and, to some extent, women benefit reproductively from engaging in extrapair mating (e.g., Greiling and Buss 2000). Indeed, women may have evolved a dual mating strategy in which they acquire investment from their primary mate and higher-quality genes for their progeny via timely sexual affairs outside the relationship when women are ovulating and thus, most likely to become pregnant from having sex. However, a dual strategy would directly violate men's evolved preference for a long-term partner's fidelity and hence, paternity certainty. Similarly, men's sexual activity outside a long-term relationship may violate women's preferences by diverting energy and resources to others. Research on sexual jealousy (Buss et al. 1992) indicates that men's long-term mate preferences are especially violated when their partners engage in *sexual* infidelity, whereas women's long-term

preferences are more negatively affected by a partner's *emotional* infidelity. Specifically, women's sexual infidelity threatens men's evolved desire for paternity certainty, whereas a man falling in love with another woman threatens his continued investment of time, energy, and resources in the current relationship.

When Long-Term Preferences Are Violated

Several things can happen when long-term preferences are violated. First, the violated person may exit the relationship or attempt to turn to or find replacement partners. These actions in turn constitute violations to the preferences of the other partner, who may then react with his or her own violation-response tactics. Over time, balance may be restored or, if not, the relationship may dissolve.

Violated individuals may also attempt to eliminate or reduce the cause of the violation. For instance, a person may threaten a partner's potential extrapair mate or engage in other mate guarding behaviors to reduce the likelihood of a partner's infidelity. Similarly, the person who has comparatively lower mate value may engage in mate retention tactics to maintain the relationship and persuade the partner of higher mate value not to leave. Along these lines, Buss (1988) identified five categories of mate retention tactics: positive inducements (e.g., "Complimented me on my appearance"), public signals of possession (e.g., "Held my hand while other men were around"), direct guarding (e.g., "Wanted to be with me all the time so that I could not meet anyone else"), intersexual negative inducements (e.g., "Became angry when I flirted too much"), and intrasexual negative inducements (e.g., "Stared coldly at a man who was looking at me").

Men with lower mate value, in particular, may resort to cost-inflicting mate retention behaviors (Daly and Wilson 1993). For example, men with lower-status jobs and lower income are more likely to inflict physical harm on their intimate partners. Women, on the other hand, use more direct guarding and other forms of intersexual

negative inducements, which are also cost-inflicting on their partners and reduce the chances that the men would have to cheat on them. Positive inducements and public signals of possession, which have been called benefit-inducing mate retention tactics (Miner et al. 2009), are displayed more by and toward partners with higher mate value, and they may provide a more positive relationship climate in which partners are likely to be satisfied. Such behavior (e.g., buying one's partner gifts, planning romantic getaways) provides the mate with more inducements to stay and keep investing in their partner and signals to others that they are no longer available.

Similarly, the partner with higher mate value can also engage in positive inducements in order to restore the equilibrium of mate values in the relationship (e.g., asking a male partner to get a higher-paying job or persuading a female partner to diet and slim down). Although confrontations can be initially distressing for both individuals, attempts to get partners to change for the better is positively associated with relationship well-being over time (Baker and McNulty 2015). If all else fails, an individual may choose to terminate a long-term relationship, especially if the individual deems that he or she has desirable alternative mates that can be attained or, if relevant, that he or she has enough resources to take care of any extant offspring. Another possibility, albeit less likely even in today's evolutionarily novel environment, would be for both partners to agree on an open or polyamorous relationship in which both partners continue investing in the current relationship (perhaps at a reduced level) while diverting some of their resources into acquiring or maintaining additional mates.

Conclusion

In summary, violation of long-term mate preferences can occur due to many factors, including errors in judgment from imperfect information and partner's deception, the relative erosion of a partner's mate value over time, and conflicts in mating strategies. The consequences of long-term mate preference violation are often dependent on

factors such as the extent of the discrepancy of mate value. In response to mate preference violations, individuals in long-term relationships may exit the relationship or seek alternatives or attempt to rectify the violation. In the modern world, there are likely many evolutionarily novel conditions – including the proliferation of virtual competitors and potential mates encountered in media outlets – that trigger such violations in increasing frequency. Future research could carefully investigate such factors that are likely increasing the incidence of mate preference violation to historically unprecedented levels. At the same time, further work looking into the effectiveness of different types of mate retention tactics may provide insights into whether the increasingly high incidence of long-term relationship failure in modern society can be curbed.

Intersexual deception; Mate preferences; Mate selection; Short-term mating; Strategic interference

Definition

Violations of short-term mate preferences refer to instances in which a person in a short-term, casual sexual relationship has mate preferences that were in place when the relationship commenced but subsequently are not being met.

Introduction

Men and women around the world have an assortment of mating preferences and strategies. These preferences and strategies have evolved to adaptively guide the selection of mates who are reproductively viable (Buss and Schmitt 1993); however, they are not always fulfilled in the mates that people actually select due to various reasons. For instance, people's initial assessments can be inaccurate, partners' relative mate value can change, and partners often face sexual conflict or strategic interference. This chapter will describe preferences for casual, sexual short-term partners and then violations of preferences due largely to intersexual deception in such relationships.

Short-Term Mating Preferences

There are a few key preferences regarding short-term, casual sexual relationships. First, both sexes have evolved to value physical attractiveness in their partners. Specifically, women are attracted to short-term mates who display visible cues of good quality genes, such as masculinity and symmetry – features indicating resistance against pathogens that cause asymmetrical development (Gangestad and Simpson 2000). Women also value size, muscularity, and physical strength in their short-term mates (Li and Kenrick 2006), which may help them obtain physical protection. Men, on the other hand, value a short-term partner's physical attractiveness as a marker for her age and health and, thus, fertility (Buss and Schmitt 1993). Therefore, both sexes especially prioritize physical attractiveness above other traits

in short-term mates, though for different adaptive reasons (Li and Kenrick 2006).

When seeking mates who are not anticipated to stay for long compared to long-term mates, women are more likely to discount the future and value present resources that she can immediately acquire through a mate with high social status or dominance (Gangestad and Simpson 2000). Women may also use short-term mating to assess and attain potential long-term relationships by casting a wider net and converting a high status and dominant short-term mate into a long-term mate (Buss and Schmitt 1993; Jonason et al. 2009; Li and Kenrick 2006). Rich men with high social dominance thus are potentially desirable short-term mates because of their ability to impart immediate resources.

Men, on the other hand, have short-term mating psychological adaptations that bias their mate preferences toward obtaining sexual variety and minimizing commitment (Buss and Schmitt 1993). Men, who are more sociosexually unrestricted than women (Gangestad and Simpson 2000), tend to be much less selective than women when seeking short-term relationships (Li and Kenrick 2006), making it more likely that casual and noncommittal sexual relations can occur. Men may also possess adaptations to minimize attachment to short-term sexual partners, such as perceiving their sexual partner to be less attractive after sexual intercourse (Haselton and Buss 2001).

Violation of Short-Term Mating Preferences

A person's mating preferences may be violated or not met for several reasons. This may sometimes occur due to poor judgment in the mate selection process – after all, trait information is not always easy to assess, but in many cases, potential partners actively induce inaccurate judgments in perceivers, constituting a form of intersexual deception that is aimed at increasing their chances of being selected as mates and increasing their own reproductive success.

More broadly, the deceptive strategies used by men and women correspond to the mate selection criteria of the opposite sex (Tookey and Camire 1991), and violations of short-term mating preferences therefore revolve around the aforementioned traits valued in short-term mates. As the veracity of mate value as inferred through displays can often only be verified in the sufficiently lengthy duration of a long-term relationship, the incentive to deceive in short-term mating may be more pronounced than in long-term mating.

Violation of perceptions of physical attractiveness. Because the successful enactment of a short-term mating strategy relies heavily on perceptions of fertility or good genes as conveyed by physical attractiveness, short-term mating preferences are violated if a person discovers that their sexual partner has grossly misrepresented their physical attractiveness. Indeed, women commonly attempt to misrepresent their fertility by wearing garments that accentuate and ameliorate sexual features (e.g., push-up bras, dresses that highlight the hourglass figure), putting on makeup (Tookey and Camire 1991), and increasingly turning to cosmetic surgery to reverse the effects of time on the face and body.

A related deceptive tactic by women to increase favorable perceptions of their fertility is through the misrepresentation of age and weight. Online dating sites are particularly telling on the nature of intersexual deceptions, as they provide individuals with the opportunity to market themselves as mates through self-constructed profiles. Indeed, analyses of online dating sites have found that women are more likely than men to downward misrepresent their age and weight – for instance, by presenting photos from up to 10 years ago – to appear more youthful and, thus, more nubile and fertile (Hall et al. 2010).

Conversely, men often deceive about the quality of their genes and physical prowess, which are both conveyed by the appearance of masculinity. For instance, men may go to the gym to improve their strength and physical fitness, exercising mainly the upper body muscles that are more aesthetically visible, and also exaggerate their posture to be more dominant or appear taller than they really are (Benz et al. 2005). Men are

also more likely than women to upward misrepresent their height and income when constructing online dating profiles. Although men generally undergo cosmetic surgery much less than women around the world, the number of men undergoing cosmetic surgery is increasing (Brown et al. 2007), and men who choose to surgically augment their looks typically strive to reconstruct a face that is more masculine and symmetrical.

Violation of perceptions of social status and dominance. As women may contemplate short-term sexual relations with men who are capable of immediately dispensing large amounts of resources, men who wish to induce short-term sexual interest in women have an incentive to deceive about their wealth, social status, and dominance. Indeed, women rely on costly ornamentation or behaviors that signal social position (e.g., expensive suits, luxury cars) and physical vigor (e.g., aggressiveness, muscular upper body) to gauge the traits that mediate resource acquisition and holding ability, namely, social status and dominance. Therefore, women's preferences for immediate resources in a short-term mate may be violated when men exaggerate their job titles or deceive about their financial status, such as when men dress as if they have more money than they do or spend more money than they can afford on a date. Further, the projection of greater social confidence, superiority, knowledgeability, and aggressiveness than is actually warranted constitutes another form of deception by men to appear more dominant and desirable (Tooke and Camire 1991), especially as short-term mates. These deceptive tactics are mirrored in online dating sites, where men often misrepresent their personal assets and social status to appear more resourceful than they actually are (Hall et al. 2010).

Violation of perceptions of expected commitment and sexual availability. To exploit men's sensitivity to cues of sexual availability, women who wish to induce men's short-term sexual interest may wear revealing clothes that show off their body more than they normally would (Benz et al. 2005; Tooke and Camire 1991). A man's short-term mating preference for easy sexual access may then be violated when a

woman signaling sexual availability withholds sex, a behavior typically described by men as being "led on."

An individual may seek to acquire a long-term mate by first entering into a relationship with a partner on the grounds that it is casual and non-committed and then attempt to raise the commitment level expected of the relationship. While both sexes may implement such a strategy to attain long-term mates, this is a tactic more commonly used by women than men (Buss and Schmitt 1993). As the supposedly short-term relationship progresses, men may encounter mates who wish to escalate commitment, and this change in desired commitment level therefore represents a violation of the commitment level that was initially expected to be low. On the other hand, men may misrepresent having their commitment, which violates women's expectations for a short-term relationship's potential for becoming a long-term relationship (e.g., Jonason et al. 2009).

Expectations of and Reactions to Mating Preference Violations

Both men and women believe that the mate selection criteria used by one sex correspond to the deceptive tactics used by the opposite sex, suggesting that people have a reasonably good intuition about the sort of violations of mating preferences that are expected to occur as predicted by evolutionary theory (Benz et al. 2005). For short-term mating, both sexes expect that men will deceive women about their financial status, while women will deceive men on their physical attractiveness.

Despite the general intuition that laypeople have about intersexual deception and these possible violations of mating preferences, many people still inadvertently end up in situations where their preferences are violated and experience negative emotions associated with these situations. When faced with strategic interference, including those that constituted violations of short-term mating preferences, both sexes were upset in the ways predicted by what men and women specifically

value in their short-term mates: women express greater upset than men when deceived about a partner's status and resources, while men experience greater upset than women about being sexually led on (Haselton and Ketelaar 2006). The experience of such emotional distress is adaptive as it compels individuals to preempt similar violations in the future, thereby aiding in subsequent mating judgments and decision-making. Interestingly, no empirical studies currently exist that examine individuals' emotional reactions to violations of physical attractiveness or the emotional outcomes of men experiencing an increase in expected commitment in ongoing short-term relationships. The predictions of this chapter therefore provide rich groundwork for fruitful future research.

Conclusion

Men and women engage in short-term mating for somewhat different underlying reasons, leading to differences in what the sexes prefer in a short-term mate. These preferences may be hindered by violations of expectations, which are often intentionally induced through intersexual deception. Given that men value sexual availability and low commitment, women value short-term partners from whom they can immediately extract resources, and both men and women value physical attractiveness in their short-term mates, individuals may misrepresent themselves on these traits and proclivities so as to increase their desirability as short-term mates and increase the likelihood that they will be sought.

Assault; Force; Physical Force; Violent

Definition

Violence is defined by World Health Organization as “the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either result in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation” (Krug et al. 2002).

Introduction

Evidence throughout history serves as a powerful reminder that contemporary violence is not a new phenomenon (e.g., Keeley 1996). Archeological evidence for violence between early humans is indisputable; human skeletons have been found (sometimes in mass burial sites) containing cranial and rib fractures that appear inexplicable except by the force of clubs and weapons that stab (e.g., Keeley 1996). Also, crafting tools necessary for inflicting severe harm on other humans, such as stone axes and wooden spears, were developed at least 400,000 years ago (e.g., Liddle et al. 2012). The origin of this violence has been an issue of considerable research and debate for centuries. Much of this research is focused on mental, social, family, and cultural influences on violence. For instance, scholars have investigated the influence of the media on the perpetration of violence or on the influence of peers and parents who model violent behavior (e.g., Buss and

Duntley 2003). Without denying the merits of these theories and influential factors, recent research has also indicated that a large proportion of violent behavior can be explained by an evolutionary psychology model.

Before discussing this model in more detail, it is important to note that all violent behavior is aggressive, but not all aggressive behaviors are violent or even necessarily negative from a cultural perspective. Consequently, violent behavior can take many forms, ranging from threatening to harm someone to its ultimate form: homicide. Most evolutionary psychologists examining violence have focused on explaining this ultimate form (Buss and Shackelford 1997).

In examining homicide, considerable attention is devoted to whether one can consider this form of violence as an unfortunate by-product of evolution or whether it can be considered as an evolutionary adaptation (Buss and Duntley 2003: 122). The by-product view on killing was firstly coined by Daly and Wilson (1988), who wrote down an evolutionary account of the different forms of homicide. Drawing on animal behavior, anthropology, and patterns of violence and murder in modern societies, they argue that although humans have the brains and minds with violent proclivities, killing is by and large, not something that evolution has selected for. Instead, they argue that it is a by-product of urges towards some other goals (e.g., Daly and Wilson 1988). For instance, male-male homicide is viewed as a by-product of evolved mechanisms underlying competition, risk-taking, and status-seeking (Daly and Wilson 1990). Many evolutionary psychologists have adopted Daly and Wilson’s position (e.g., Crabb 2000). However, some others, such as Duntley and Buss (2005), have rejected this by-product hypothesis and have instead put the adaption view forward. They argue that humans possess psychological adaptations for killing that have evolved because they successfully managed to solve specific, recurrent adaptive problems in our ancestral past. Or to put it differently, adaptations for killing have been selected for because individuals who possessed those adaptations were reproductively more successful than individuals who did not in relevant historical environments.

These adaptations form the so-called Homicide Adaption Theory (e.g., Duntley and Buss 2005).

Determining whether a particular behavior, in this case killing, is generated by specialized adaptation or generated as a by-product of other adaptations can be exceedingly difficult. It is also important to note that this is also the case – but to a lesser extent – when examining other violent behavior, such as rape. In this context, the discussion on whether a particular violent behavior is an adaption or a by-product is set aside; regardless of the result, similar effects of cues of infidelity, reproductive value, kinship, and other conflict-related variables should be expected.

Generally, evolutionary psychologists rely on two theoretical models for explaining violent occurrence: sexual selection and parental investment theory.

Sexual Selection Theory and Parental Investment Theory

Natural selection explains the evolution of complex traits as a result of heritable variations that influence differential survival. In any given population, some organisms are more likely to survive and subsequently pass on their genes than are others. Although survivability is important, this is not the sole of one's fitness (i.e., one's success in passing on his or her genes to the next generation), at least not among sexually reproducing organisms. Selection will also operate on traits that affect one's reproductive potential, i.e., it promotes evolution by choosing features that assist the species to gain better and more sexual access to mating opportunities. To put it more bluntly, fitness is closely related to the number of offspring produced.

Sexual selection operates via two mechanisms: intersexual selection and intrasexual competition. Intrasexual competition refers to competition between same sex rivals for access to mating opportunities. Opportunities and traits that improve one's chances of succeeding in such competition will be selected for. In contrast, intersexual selection consists of members of one sex attempting to impress members of the other. This

form of sexual selection is generally regarded as being responsible for the development of more expensive, dangerous, competitive traits, both morphological (e.g., weapons like antlers or the colorful tail in the case of the peacock) and psychological (e.g., risk acceptance) (e.g., Daly and Wilson 1988: 275).

However, what governs the operation of sexual selection is the relative parental investment of the sexes in their offspring. How these investments differ and what kind of effect these differences have is described by the parental investment theory (e.g., Trivers 1972). In all mammals, females exhibit greater minimum obligatory parental investment in their offspring than males. Females must devote considerable time and energy to their offspring due to internal fertilization and gestation, which is often followed by a period of nursing, whereas the minimum obligatory investment by males is the contribution of sperm. As a consequence, females are far more discriminating when choosing a male to mate or as Mealey (2003: 86) formulates it: for females, it is the “quality” of coupling that is more important than the “quantity.” Consequently, females engage in intrasexual competition for the highest quality mates (e.g., men with good genes who produce offspring with high prospects of survival or, for instance, men with high status who signal the ability to provide for a woman and her offspring) (e.g., Miller 1998). Due to the fact that females represent a limiting factor for male reproductive process, males are then also predisposed to riskier intrasexual competition for mating opportunities.

Male-Male Violence

Competition for mating opportunities entails the contestation for those resources that can be converted into reproductive opportunity, whether because they are directly attractive to females or because they help quell rival males (Wilson and Daly 1985: 60). For instance, status, honor, and reputation play an important role. Evidence suggests that high status in men has, for example, historically translated into having more access to food, better territory, and greater social support,

thus serving as an honest signal of a man's ability (but not necessarily intent) to provide for a woman and her offspring (Daly and Wilson 1988: 282). In other words, males will often compete with other males for dominance and other resources that are attractive to potential mates. For instance, in modern day societies, they compete over means including professional qualifications, highly paid, or prestigious jobs (Campbell 2011). Losing these competitions or walking away from them can be catastrophic in the currency of survival and reputation. This is especially the case for young males (16–24 years of age), which are in that portion of their lifespan when reputations are made and mates are acquired (Campbell 2011).

There are two things that determine the ferocity of this competition and whether this competition over resources turns out violent and even into homicide: the value of the object being fought over and the risks involved. Given that the reward of victory is high (and the consequence of losing is little or no chance of reproducing), the more intense the competition, the higher the likelihood of the use of violence as a competitive strategy. Male-male homicide is then also viewed as a product of evolved mechanisms underlying high intense competition, risk-taking, and status-seeking (Daly and Wilson 1990). However, it is important to note that rivalry and competition over mating opportunities can trigger nonlethal aggression as well. In a study of mate guarding, for example, men picked a fight with the rivals who showed interest in their mates and threatened to hit rivals who were making moves on their mates (Buss 1988).

Female Aggression and Violence

Despite the overrepresentation of men in statistics regarding violent behavior, it is important to recognize that violence is not an exclusively male behavior (e.g., Wilson and Daly 1985). While violence perpetrated by males is often described as a “higher stakes, higher risk” enterprise (Daly and Wilson 1988: 140), we should not forget that females also engage in intrasexual competition for the highest quality mates. However, since the

potential costs associated with physical violence are often higher for women than for men – the death of a mother has more lethal consequences for children's survival than the death of a father – women often opt for other forms of violence when competing for mates. They employ more often tactics involving indirect or relational aggression, which consists of verbal derogation, gossip, spreading rumors, and other nonphysical forms of ostracism and stigmatization in which the victim is often “attacked” indirectly, thereby reducing the likelihood of retaliation (Björkqvist et al. 1994). This does not mean that women experience less anger than men, rather that they have a higher threshold for employing violence as a competitive tactic (e.g., Archer 2004).

Intimate Partner Violence

Not all violence that occurs in the context of mating is intrasexual. Male violence directed at women, most often intimate partners, is a phenomenon that must be addressed. According to Daly and Wilson (1988), men perpetrate violence against their wives or girlfriends under two key conditions: the observation or suspicion of sexual infidelity (i.e., cuckoldry) and when the woman is terminating the relationship. Although these are two distinct mechanisms, they are – from the perspective of natural selection – similar: the important commonality is that the man loses control of female reproductive capacity and hence loses ground in the reproductive competition between men (Daly and Wilson 1988: 279).

Until very recently, men could never be certain that their putative offspring were genetically their own. Therefore, the possibility of cuckoldry has represented a serious adaptive problem for men throughout our evolutionary history. The costs of cuckoldry for the male's fitness are severe; it includes the misdirection of the male's time, effort, and resources to rearing a rival's offspring. Moreover, it includes time, effort, and resources that the man spent attracting his partner, and reputational damage if such information becomes known to others (e.g., Daly and Wilson 1988). Consequently, men developed strategies and

tactics aimed at avoiding cuckoldry and decreasing paternity uncertainty. In the animal world, male birds, for instance, follow their mates closely during the breeding season, which is interpreted by ornithologists as “mate guarding” behavior with its fitness-promoting function as paternity assurance (Daly and Wilson 1998). Fitness promotion also suffers when a woman is terminating the relationship due to the loss of a reproductively valuable woman to a potential rival (Buss and Shackelford 1997: 616).

Most researchers have lumped these two mechanisms together because the potential violent reactions in both scenarios are motivated by male sexual proprietariness, a sense of ownership men have over women, encompassing not only episodes of jealous arousal but also presumptions of entitlement and inclinations to exercise control and prevent threats of trespass or usurpation (e.g., Daly and Wilson 1988). This sexual proprietariness of males is one of the most frequently cited causes of intimate partner violence, both physical and sexual (e.g., Daly and Wilson 1988).

Violence Against Children

When discussing violence in the context of families, it is important to consider the genetic relatedness of family members. According to kin selection theory (e.g., Hamilton 1964), organisms should be more altruistic and less competitive toward others as a function of their genetic relatedness. Helping a genetic relative and increasing that person's fitness, even at a cost to oneself, can ultimately be beneficial to the altruist because of the genes he or she shares with the beneficiary. In other words, increasing a genetic relative's fitness will result in some of one's own genes being passed on to future generations, thereby increasing one's inclusive fitness. Despite the lower levels of competition between genetic relatives predicted by kin selection theory, competition and violence do occur among family members. One form that warrants our attention is the killing of same-species offspring, which has been observed among many species of mammals. For

instance, male lions kill the young when they displace another male and take over a female (Buss and Shackelford 1997: 610). These acts might be attributed by some academics to the “failure of engagement of the normal mechanisms of parental love” (quoted in Daly and Wilson 1998). However, even these extreme acts of violence can be approached via an evolutionary perspective. Given the high costs associated with investing in offspring, human psychology is likely to have been shaped in such a way as to forego paying these costs when the desired outcome of investment (i.e., a reproductively capable adult) is unlikely to occur (Daly and Wilson 1988). In other words, parents can terminate their investment in their infants in order to preserve their finite time and resources for others. Examples of adaptive problems that infanticide solves are, for instance, avoiding to invest in physically subpar offspring who were unlikely to convert parental resources into their own reproductive success (e.g., those who were deformed, diseased); avoiding to invest in offspring when external conditions hampered the infant's survival (e.g., food scarcity, lack of an investing father, harsh season); and eliminating competition for older or more viable offspring when resources are scarce (e.g., twin births or when birth spacing was too close) (Duntley and Buss 2011: 402).

Another important causal context that has been identified is the Cinderella effect, i.e., the phenomenon of higher incidence of different forms of child-abuse and mistreatment by step-parents than by biological parents (e.g., Daly and Wilson 1996). Abuse from stepparents has been immortalized in children's stories, the most common being that of Cinderella, who was abused by her wicked stepmother (Buss and Shackelford 1997: 616). Some evolutionary psychologists describe this effect as an adaptive strategy to avoid parental investment in a rival male's infant (Duntley and Buss 2011). Others describe it as a remnant of an adaptive strategy in which males frequently kill the offspring of other males in order to bring their mothers into estrus and give the male a chance to fertilize her himself. There is both supporting evidence for this theory and criticism against it.

Violence During War

Any comprehensive discussion of human violence would be incomplete without an analysis of war. The killing of one person by another may be accidental and perhaps a by-product of aggression but intergroup conflict or warfare might be an adaption in itself. Although it is difficult to determine when humans (especially men) began engaging in warfare, the raiding behavior of other species suggests that warlike behaviors have been a part of the human behavioral repertoire for the majority of, if not the entirety of, our evolutionary history (e.g., Keeley 1996). This behavior was first reported by Goodall et al. (1979) in Tanzania in the 1970s; in a long-term study, she shows several incidents of murderous “gang violence” among chimpanzees. In one case, the adult males of one community systematically attacked and killed the males of another group over a period of years, with the victorious group eventually absorbing the remaining victims. Raids on neighboring communities are also common in anthropologists’ accounts of small-scale human societies (Wrangham and Glowacki 2012). These often follow the chimpanzee template; a small team of men leaves its home grounds, sneaks up on the neighbor, and tries to kill one or more of them.

Moving from studies of chimpanzee coalitional violence and that of small-hunter gatherer societies to understanding modern warfare from an evolutionary perspective is, however, far from straightforward. At least three evolutionary factors might play a role (Fishbein and Dess 2003). First, one of the major innovations in evolutionary psychology is the elaboration of the kin selection theory (inclusiveness fitness) (e.g., Hamilton 1964) and its relationship to social behavior (Wilson 1975). This theory suggests that, given the opportunity, individuals show greater selfish restraint, less aggression, and greater altruism toward closer relatives. The direct social implication of this theory is that the human species are essentially designed to be ethnocentric – to favor our own group as opposed to others (Fishbein and Dess 2003: 170). In turn, this in-group favoritism can lead to a second – interrelated – factor: out-group hostility. In

other words, coalitional aggression against the out-group can be the direct result of the need for acquiring or defending resources relevant to the in-group’s survival and reproduction (i.e., protecting the inclusive fitness of the in-group). In other words, eliminating rival groups to gain access of reproductively relevant resources, such as food or territory, produce very long-term benefits and as such outweighed the costs in the currency of fitness (Buss and Shackelford 1997: 609).

Lastly, humans differ also significantly from other mammals, to the extent in which they accept authority (Fishbein and Dess 2003). One important aspect is the psychological internalization of what authorities tell us. We personally take on beliefs and values of authorities and in turn, transmit these to others over whom we have authority, reinforced by conceptual or symbolic materials (Waddington 1960). Additionally, the connection between authority acceptance and the development of prejudices and discriminant behavior is obvious in connection with out-group prejudices and discrimination, and it forms a strong motivation for going to war.

Despite these evolutionary predispositions that facilitate – especially men – going to war, potential injury and loss of life still represent substantial costs that are likely to select against such behavior unless certain conditions are met to offset these costs. Tooby and Cosmides (1988) have argued that there are at least four conditions. First, the average long-term gains in reproductive resources should outweigh the reproductive costs of war. Second, there should be a steady belief that one’s group will be victorious. Third, one should receive benefits that commensurate with one’s contribution and degree of risk taken. Lastly, there should be an inability to accurately predict which group members will live or die. In short, conditions that increase the perceived benefits and decrease the perceived costs will facilitate the willingness of men to engage in warfare.

Conclusion

Despite the accounts of violence and how it solves a number of specific potential adaptive problems

described above, a few things are worth noting. First, although violent behavior might be influenced by genetics and biology, that does not serve as a justification for such behavior (see Wilson et al. (2003) for a discussion). Similarly, genes do not cause men to commit violent acts; if they do anything, they predispose them to do so. Whether men carry them out will depend on their previous experiences, cultural context, and other genetic predispositions (e.g., Elbert et al. 2017). For instance, even though men are disposed to behave more violently than women, it is not the case that every man will react with violence when catching his partner with another person. Moreover, cultural values play an important role in calculating the (reputational) cost of violence. For instance, suicide is taboo in many cultures, which is likely to suppress its occurrence. Violent behavior is, therefore, one strategy within a menu of strategies, activated only under a highly specific set of co-occurring conditions (Buss and Duntley 2003: 120). Third, it should be noted that humans and many other species also have a tremendous capacity for cooperation. Far more time is spent engaging in cooperation, or at least peaceful coexistence, than is spent engaging in violence (Liddle et al. 2012). However, by studying violence from an evolutionary perspective, analyzing the contexts in which it occurs and the stimuli that influence its occurrence, we can gain a better understanding of the mechanisms that produce violence, thus putting us in a better position to limit the activation of such mechanisms (Liddle et al. 2012).

[Intimate partner violence](#); [Physical aggression](#); [Sexual aggression](#); [Sexual conflict](#); [Sexual jealousy](#)

Definition

Ancestral men may have benefitted by inflicting physical and sexual violence against women to manipulate women's sexual behavior or to circumvent female sexual choice. Because gestation occurs within females, women are especially sensitive to the risk of violence and associated injury. The reproductive costs of physical harm are greater for women, and, therefore, some men use violence or threats of violence to control women's behavior.

Introduction

Mate guarding behaviors are intended to discourage an intimate partner from committing infidelity, defecting from the relationship, or being poached by a rival (Buss 1988). Men use mate retention behaviors to combat the risk of the cuckoldry (unwitting investment in a rival's genetic

offspring) and to minimize resource loss, whereas women use mate retention behaviors to retain a partner's long-term investment. Violence is a mate guarding strategy, mostly inflicted by men against women, to control a partner's sexual behavior or autonomy. Women are especially vulnerable to violence, and this is reflected in their reactions to threat of violence. For example, women respond to fear differently than men (McLean and Anderson 2009). Because women's reproduction depends on their ability to survive, women are especially fearful of risky or violent situations. Once conception occurs, men no longer need to survive to be reproductively successful, whereas women's survival is required for gestation and childrearing. Thus, women may have evolved psychological mechanisms that motivate them to avoid physical harm. Men may have coevolved mechanisms to exploit women's fear for their own reproductive benefit. By inflicting or threatening to inflict violence, men coerce women into sexual fidelity, maintaining the relationship, or securing sexual access (Buss 1988; Wilson and Daly 1993). Women cannot afford to risk physical injury, so acquiescing to men who use or threaten violence may sometimes be an effective self-defense strategy. Men use physical violence against women, including physical abuse or threats of physical abuse, to minimize paternity uncertainty. Men use sexual violence against women, including sexual coercion and rape, to gain sexual access without investing resources into the woman. In sum, both physical and sexual aggression by men against women function to control and manipulate female sexual behavior.

Physical Violence as Coercive Control

Male sexual jealousy is a primary motivator for men's physical aggression against women (Daly and Wilson 1988). Because gestation occurs within women, men are at risk of investing time and resources into offspring to whom they are genetically unrelated. Thus, jealousy is produced by an evolved mechanism to alert individuals to potential or actual infidelity by their partner (Buss 2000). When men suspect or discover sexual infidelity, they are more likely than women to inflict violence

against their partner (Daly and Wilson 1988). Fear of physical harm or death motivates women to avoid their partner's physical attacks, thus discouraging women from pursuing infidelities. Wilson and Daly (1993) suggest that by inhibiting a partner from committing sexual infidelity with aggression, men control with whom the woman reproduces. Additionally, through controlling a woman's sexual behavior, men reduce the risk of cuckoldry or mate poaching by a rival.

Sexual Violence as Coercive Control

In some instances, men use sexual aggression against women to bypass resource investment and female sexual choice (Thornhill and Palmer 2000). Thornhill and Palmer (2000) review the hypothesis that rape is produced by specialized adaptation, which motivates men to rape in specific circumstances. Rape may have been adaptive for ancestral men because it increased reproductive opportunities and required little time or resources to secure sexual access to a female. By circumventing female choice, sexual aggressors control a woman's reproduction. As with physical violence, women's fear of rape is related to perceived risk of physical harm or death (Pryor and Hughes 2013). Women's fear of injury or death may inhibit them from engaging in self-defense during a rape. Additionally, partner rape sometimes occurs in the context of sperm competition (Goetz and Shackelford 2006). In those cases, men engage in sperm competition to attempt to affect their partner's reproduction before or after an actual or suspected infidelity.

Conclusion

Physical injury is particularly detrimental to a woman's reproduction because gestation occurs within women. Thus, women may have evolved psychological mechanisms that make them especially sensitive to risky situations. Men may have coevolved mechanisms that exploit women's fear of harm, for their own reproductive benefit. For example, men inflict physical and sexual violence against a woman to discourage her from

committing infidelity, abandoning the relationship, or to circumvent female sexual choice. In sum, violence is inflicted by men against women to control a woman's sexual behavior.

Violence from Women's Kin

Rachel M. James and Todd K. Shackelford

Synonyms

[Daughter-guarding](#); [Homicide](#); [Honor killing](#);
[Parent-offspring conflict](#)

Definition

Genetic kin benefit from monitoring and defending female family members. Daughter-guarding and sister-guarding, for example, in the forms of vigilance or violence, function to control a woman's sexual behavior, thereby regulating with whom she reproduces. However, violence from kin members is sometimes directed toward the woman. Sometimes this violence includes “honor killing,” in which a woman is killed to restore her family's reputation, typically on suspicion that she has participated in illicit or socially unacceptable sexual behavior.

Introduction

Females are a reproductive commodity. For example, although sons have the ability to produce more offspring than daughters, daughters have more certain opportunity to reproduce than sons. Because women invest more heavily in offspring than men, women are more selective when choosing mates. Men compete with one another to secure sexual access to women. Thus, safeguarding female kin may have been ancestrally adaptive (Perilloux et al. 2008). Genetic kin can be reasonably certain that a female relative will have opportunities to produce offspring whereas a male relative may not. By performing behaviors to control a female relative's sexual behavior and thereby protect their reproductive value, ancestral kin members increased their fitness.

Kin's female-directed guarding behavior sometimes becomes violent, and occasionally homicidal. Homicidal revenge for a kin member's abuse or death has been documented in many cultures (Daly and Wilson 1988). Engaging in violence against those who threaten or injure female kin protects the woman's future reproductive potential. For example, proximity to kin is associated with lower rates of female-directed abuse and homicide (Daly and Wilson 1988). Additionally, Daly and Wilson (1988) report that women are more likely to use violence against an abusive partner when the woman's genetic kin reside nearby, suggesting that proximity to kin translates into protection for the woman,

and may encourage her to engage in violent self-defense. However, sometimes culture and reputation lead kin to kill women, a practice referred to as “honor killing.” Honor killings are primarily perpetrated by fathers or brothers against female kin to restore and protect the family’s honor (e.g., a man kills his daughter who is suspected of having premarital sex). From an evolutionary perspective, killing an offspring may have been ancestrally adaptive, for example, if the absence of that offspring made available resources that could be invested in offspring with a more promising reproductive future.

Guarding Female Kin

Mate guarding refers to behaviors performed to reduce the risk of an intimate partner being poached, committing infidelity, or abandoning the relationship (Buss 1988). The daughter-guarding hypothesis suggests that humans have evolved psychological adaptations to be especially sensitive to and protective of a female kin member’s sexual behavior and reputation (Perilloux et al. 2008). Because female kin more reliably reproduce, kin members attempt to exact more control over a female’s mating behaviors than over a male’s mating behaviors (Faulkner and Schaller 2007; Perilloux et al. 2008). Controlling a daughter’s sexual behavior, for example, may have been ancestrally adaptive for kin because females do not face maternity uncertainty, thus increasing the likelihood that the female kin’s offspring will share the genes of her kin. Additionally, because offspring development occurs within women, using violence to protect female kin from an abusive partner may have been selected, given that harm inflicted on a woman might decrease her reproductive success and, consequently, the success of her genetic kin. Women who have proximate kin, or more immediate familial protection, are less likely to be killed or injured by a partner (Daly and Wilson 1988). One study of South Asian women immigrants reported that loss of social support after migration reduced the likelihood that immigrant women would seek help for partner abuse (Ahmad et al. 2009).

Retaliation and Revenge

In some cultures or religions, kin members (particularly fathers or brothers) kill a daughter or sister to restore “honor” to the family. For example, Chesler (2010) reported that 57% of Muslim honor killings are motivated by perceived sexual impropriety by the victim, such as engaging in an extramarital affair. In the United States, 56% of honor killings are committed by a father for the daughter’s perceived misbehavior, such as dating outside the family’s culture or religion (Hayes et al. 2016). Although it seems counter-intuitive to kill offspring, the restoration of the family’s social status may improve the reproductive future of other family members. If a daughter’s sexual reputation has been tarnished, she might no longer be a reproductive commodity to her family. Her death might therefore benefit the rest of the family by freeing up resources otherwise consumed by her.

Conclusion

Individuals exercise greater vigilance over close genetic kin than non-related individuals or more distant kin (Faulkner and Schaller 2007). Vigilance and violence by a woman’s kin function to control the woman’s sexual behavior. To increase the replicative success of shared genes, kin may defend females by inflicting violence against an abusive mate or by monitoring a woman’s clothing, for example. Guarding of females by kin is intended to increase the power parents and relatives have in determining with whom the guarded female mates and reproduces (Perilloux et al. 2008). In rare instances, however, kin kill their daughters or sisters to restore social status or “honor” to the family.

Violence to Control Women's Sexuality

Nicole Barbaro
Department of Psychology, Oakland University,
Rochester, MI, USA

Synonyms

[Intimate partner violence](#); [Sexual coercion](#)

Definition

Physical, psychological, or sexual violence employed by men that, ultimately, functions to increase the mating success of the perpetrator and/or decreases the likelihood of a woman copulating with other men; Manifest psychology and behavior to prevent, correct, or anticipate female infidelity.

Introduction

Psychological perspectives on violence against women, broadly understood, maintain that violence may be employed to control women's sexuality. The ultimate motivations underpinning men's violence as a means to control women's sexuality, however, differ across subdisciplines of psychology. Mainstream standard social science perspectives posit that violence perpetrated by men against women is motivated by men's attempts to dominate and control their partners, more generally, and that this expression of dominance is, ultimately, a learned behavior that is the product of men's social roles (Ali and Naylor 2013). An evolutionary psychological perspective, in contrast, posits that men's violence against women is the product of evolution by natural selection in that men's motivations for violence perpetration are, ultimately, sexual in nature – though, not (necessarily) consciously (reviewed in Goetz and Shackelford 2009). From this perspective, men's violence is employed against women, primarily in intimate partnerships, as a means to prevent, correct, and anticipate women's infidelity (Shackelford 2003), whereby violence employed by men functions to increase his mating success with the woman or decreases the likelihood of the woman copulating with other men (Barbaro and Shackelford 2016; Camilleri and Quinsey 2012).

The theoretical and empirical findings that evolutionary psychologists have amassed over the preceding decades generally fall within two domains of focus. One area of research primarily focuses on identifying recurrent adaptive problems of reproduction faced by males for which violence may have been used as an adaptive solution. Another area of research focuses on the how, exactly, violence solves relevant adaptive problems of reproduction faced by ancestral men. Evolutionary research on men's violence tends to highlight the replicative benefits afforded by men employing violence, with the later domain of research, in particular, providing a valuable framework from which various types of behavior can be classified and understood. Evolutionary research on the ultimate underpinnings of men's

violence draws upon several foundational evolutionary theories and principles. In this entry, I briefly review the theoretical and empirical support for an evolutionary psychological perspective on men's violence against women as a means to control women's sexuality.

The Adaptive Problem

Physical and sexual aggression against women is often perpetrated by a current or former romantic partner. Parental investment theory (Trivers 1972) has been leveraged as the dominant theoretical approach for understanding female-directed violence. Fundamental biological differences, or asymmetries of reproduction, between men and women hold considerable explanatory power for understanding why men, in particular, aggress against women. One fundamental asymmetry is that of fertilization and gestation of offspring occurring in women, rather than men. One substantive consequence of this reproductive asymmetry is *paternity uncertainty* – ancestral men could not have been certain that their offspring with a romantic partner were, in fact, genetically their own. Ancestral women, in contrast, had maternity certainty. Paternity uncertainty places men at risk for cuckoldry – the unwitting investment of resources into genetically unrelated offspring. Cross-cultural evidence of infidelity rates and paternal discrepancy rates indicate cuckoldry was a recurrent feature of human evolutionary history (reviewed in, Goetz et al. 2008). Because men often invest substantially in their putative offspring, a partner's infidelity (or probability of committing infidelity, or perceived risk of a partner's infidelity) places men at risk for incurring substantial reproductive costs (Daly and Wilson 1988; Smuts 1992). Put differently, paternity uncertainty was likely a fundamental adaptive problem of reproduction faced by ancestral males.

Because of the potential costs associated with cuckoldry, men are sensitive to contexts in which exclusive sexual access to their female partner may be threatened and, thus, situations for which the risk of cuckoldry is relatively greater. Over evolutionary history, a recurrent context in which men's exclusive sexual access and paternity is threatened is female infidelity (Shackelford

2003). Men's aggression, more generally, is largely deployed to solve adaptive problems (Buss and Shackelford 1997) and, specifically, aggression against an intimate partner can facilitate exclusive sexual access to the in-pair partner to correct or prevent female infidelity. Therefore, men's perceptions of their female partners' infidelity – actual or imagined – is a primary cue to cuckoldry risk and, therefore, a primary context in which men deploy aggressive behavior in intimate relationships.

Consistent with the hypothesis that men employ violence in response to cues of female infidelity, research has demonstrated, for example, that men who perceive a greater risk of partner infidelity perpetrate more frequent partner-directed violence (Kaighobadi et al. 2009). Men's accusations of their partner's sexual infidelity predict men's violence against their partner (Kaighobadi et al. 2008). And, notably, cross-cultural research shows that male sexual jealousy (resulting from actual or imagined partner infidelity) is a leading cause of female-directed violence and partner homicide (Daly et al. 1982; Buss 2000).

Further evolutionary consequences of female infidelity in intimate relationships include sperm competition. Sperm competition occurs when the sperm of two or more males simultaneously occupy a female's reproductive tract and compete to fertilize the ova (Parker 1970). A recurrent context for sperm competition in humans is female infidelity (Baker and Bellis 1995). Because human males often invest considerable resources in their putative offspring, the costs of cuckoldry can be substantial. Dual-mating by females may have instantiated selection pressures on males to combat sperm competition. Ancestral men that were relatively more vigilant of cues to female infidelity – and thus, sperm competition risk – would have incurred an adaptive advantage over men who were less vigilant of cues to female infidelity. Regarding psychological and behavioral outputs, application of sperm competition theory has provided considerable evidence for the relationship between female infidelity and sperm competition risk and men's use of aggression and coercion toward romantic partners'

infidelity (reviewed in Pham and Shackelford 2014). Put differently, empirical findings support the hypothesis that men employ aggressive and coercive behaviors judiciously in the context of intimate relationships to increase their success in (actual or imagined) sperm competition, especially when risk of cuckoldry is greatest (e.g., after separation from their partner).

Violence as an (Ancestral) Solution

Selection for employing violence in the appropriate contexts necessitates that violence reliably solved the relevant adaptive problems of reproduction over evolutionary history and conferred some sort of replicative advantage for men. As mentioned above, the ultimate evolutionary underpinnings of female-directed violence posits that men may use violence to prevent, correct, or anticipate female infidelity. In accord with this hypothesis, functional accounts of female-directed violence are also necessary for a comprehensive evolutionary theory of men's violence to control women's sexuality. One domain of research therefore focuses on how, exactly, violence might have solved the adaptive problems of reproduction for men (e.g., exclusive sexual access to a woman), and the replicative benefits afforded to violent men in reproductive contexts. Comparative research on nonhuman primates, underpinned primarily by sexual conflict theory, provides a foundation for which functional organization of female-directed violence can be integrated with research on humans (see Barbaro and Shackelford 2016).

Sexual conflict occurs when the reproductive interests of males and females differ, such that the optimal outcome of a trait is different for each sex (Parker 2006). Sexual conflict is common in mating situations because of the differences in size and requisite energy costs for developing sperm and ova. Because of asymmetries of minimum obligatory parental investment (Trivers 1972), in most sexually reproducing organisms (including humans), the reproductive success of males is limited by the number of copulations with fertile females. For females – because production of ova is finite – their reproductive success is limited to the time and energy required to rear offspring

(Bateman 1948). For example, if a man were to copulate with twenty different women over the course of a year, he has the reproductive potential to sire upwards of twenty offspring. If a woman, in contrast, were to copulate with twenty different men over the course of a year, she has the reproductive capacity to carry only a single pregnancy to term.

Because male reproductive success is dependent upon sexual access to females and maintaining exclusive sexual access to an in-pair partner, selection may have favored male traits and manifest behavior that facilitate (exclusive) sexual access to women by means of force (Muller and Wrangham 2009). This category of manifest behaviors are broadly referred to as “sexual coercion” (Smuts and Smuts 1993). Within this functional framework, sexual coercion is defined as the use or threat of *male force* to secure and maintain *sexual access* to a female and *constrain female promiscuity* (Smuts and Smuts 1993). Importantly, this definition specifies the conditions under which female-directed violence can be interpreted as a form of sexual coercion (Muller et al. 2007). These conditions include female-directed violence intensifying in reproductive contexts (e.g., in humans, committed relationships), female-directed violence being targeted at fertile females (e.g., in humans, reproductive age women), and higher rates of female-directed violence being associated with higher copulation rates with that female (Smuts and Smuts 1993).

This functional framework of sexual coercion is the predominant explanation for female-directed violence in nonhuman primates (Muller and Wrangham 2009), such that female-directed violence employed judiciously in the appropriate contexts may solve the adaptive problem of obtaining (exclusive) sexual access to a female. Research in nonhuman primates documents a positive relationship between female-directed violence and male mating success. Put differently, violent behavior perpetrated by a male against a female is purported to function as a form of sexual coercion (Muller and Wrangham 2009). In Japanese macaques (*Macaca fuscata fuscata*), for instance, research has shown that dyads in which a male perpetrated violence against a fertile

female had higher copulation rates than dyads in which a male did not perpetrate violence against a fertile female (Soltis et al. 1997). Similarly, research on chimpanzees (*Pan troglodytes schweinfurthii*) documented a positive association between the frequency of violence against fertile females – operationalized as charging displays, chases, and contact aggression – and the number of copulations the perpetrating male secured with those same females. Additionally, individual males secured more frequent copulations with females against whom they were more (vs. less) violent (Muller et al. 2007).

Research applying the sexual coercion framework proposed by Smuts and Smuts (1993) has been subject to relatively less empirical effort in humans, however. Important differences in mating systems between humans and nonhuman primates should be taken into consideration as well, such that, compared to nonhuman primates, humans display several unique characteristics. Although women are less promiscuous than some other nonhuman primate females, mated women can secure genetic and nongenetic benefits from extra-pair copulations (Gagnestad and Thornhill 2004). Men and women also form pair-bonds in the context of multimale, multi-female groups, but pair-bonded men and women sometimes spend extended periods of time physically apart, providing opportunities for women to secure extra-pair copulations surreptitiously. Moreover, because ovulation in humans is (relatively) concealed in comparison with most nonhuman primate species, sexual behavior in humans is not limited to only the fertile phase of the menstrual cycle (Thornhill and Gangestad 2008).

These differences of mating systems have consequences for the conditions for which female-directed violence may be an adaptive solution. Concealed ovulation in humans consequently results in female-directed violence not being constrained to only times of high fertility, as in most nonhuman primates with overt signs of ovulation; but rather, women of reproductive age, more generally (i.e., women that have greater *potential* to conceive), are at greater risk of male violence than nonreproductive age

women (Peters et al. 2002). Additionally, because men often invest substantially in their putative offspring, a partner's infidelity places men at risk for incurring substantial costs (Daly and Wilson 1988; Smuts 1992), such as cuckoldry (Buss and Shackelford 1997). Men must therefore solve both the problems of obtaining sexual access and maintaining exclusive sexual access once a partner is acquired. This unique combination of features has been argued to render male sexual coercion especially likely to occur in humans (Smuts 1992).

The “sexual coercion” hypothesis has also been proposed as a functional explanation for female-directed violence in humans (Barbaro and Shackelford 2016; Camilleri and Quinsey 2012) and propose two specific ways in which violence may solve adaptive problems of sexual access. There is limited empirical data for humans addressing these possibilities, however. Female-directed violence can be classified as *direct coercion* or *indirect coercion* (Muller and Wrangham 2009). Direct coercion refers to force which increases the mating success of, or probability of mating for, the perpetrator. Indirect coercion refers to force which decreases the likelihood of the woman securing or soliciting copulations with a man other than the perpetrator. Direct and indirect forms of sexual coercion are not mutually exclusive. For instance, Camilleri and Quinsey (2012) argue that, in human relationships, physical violence may function as direct coercion by increasing the probability of copulating with an in-pair partner, or physical violence may function as indirect coercion by decreasing a woman's promiscuity and probability of extra-pair mating, or both. In support of the direct coercion hypothesis for humans, Barbaro and Shackelford (2016) show that the frequency of male-perpetrated female-directed violence is positively associated with greater in-pair copulation frequency in romantic relationships. Additional findings show that men who perpetrated physical violence against their romantic partner in the previous 1 month (versus men who did not perpetrate physical violence against their romantic partner) secured more copulations per week, on average (Barbaro and Shackelford 2016).

Research has yet to investigate whether female-directed violence in human relationships also functions as *indirect coercion*, however. If male-perpetrated violence does, indeed, function as a form of indirect sexual coercion, then female-directed violence should be associated with a decrease in a woman's promiscuity, or probability of infidelity. In accordance with the sexual coercion framework (Smuts and Smuts 1993), if male-perpetrated violence functions as hypothesized, then women with violent partners should have fewer opportunities to secure extra-pair copulations (e.g., have fewer male acquaintances, spend less time with other men) (see Barbaro and Shackelford 2016; Camilleri and Quinsey 2012). Research addressing the functional nature of female-directed violence, in accord with research in nonhuman primates, will likely be a profitable empirical endeavor.

Conclusions

An evolutionary psychological perspective proposes that the function of, and motivation for, men's violence against women is, ultimately, sexual in nature. Put differently, men judiciously employ violence – primarily against former or current romantic partners – to correct, prevent, or anticipate female infidelity (Shackelford 2003), whereby violence employed by men solves the adaptive problems of (exclusive) sexual access by functioning to increase his mating success with the woman (Barbaro and Shackelford 2016). Evidence therefore suggests that over evolutionary history men who employed violence judiciously, on average, conferred replicative advantages compared with men who did not judiciously employ violence, in part, to control women's sexuality.

Definition

Viruses are smallest infectious agents comprising genetic material (DNA/RNA, never both) surrounded by a protein coat (Brooks 2010).

Introduction

Viruses are submicroscopic infectious agents which are obligate intracellular parasites. They are metabolically active and can replicate, only inside the host cell (White et al. 1994). The extracellular (transmission) phase alternates with the intracellular (reproductive) phase. Tobacco mosaic virus (TMV) was the first virus to be discovered (Lecoq 2001). Ivanoski (1892) saw that extracts from infected leaves remained infectious after filtration through bacterial filters. Beijerinck (1898) suggested to categorize the causative agent for tobacco mosaic disease as “virus” (Lecoq 2001).

Structure

Virion is the infectious virus particle consisting of a nucleocapsid core. Virions may be surrounded by a lipoprotein envelop (Brooks 2010). The nucleic acid can be single-stranded or double-stranded RNA or DNA. Nucleic acid codes for structural (capsid, envelop proteins, matrix protein) and nonstructural proteins (enzymes like replicases, proteases, and transcriptases) that are important for viral life cycle (White et al. 1994).

Viral capsid is composed of morphological units called capsomeres. Depending upon the arrangement of these capsomeres around the nucleic acid, a virus can have icosahedral symmetry (Fig. 1), helical symmetry (Fig. 2), or complex symmetry. Lipid part of envelop is acquired from the host cellular membranes and the glycoprotein part is coded by

the viral nucleic acid. Capsid and envelop provide protection and stability to the viral nucleic acid and also help viral interaction with the host cell.

Classification

Viruses can infect plants, animals, and microbes as well. Common plant viruses are TMV, Tomato spotted wilt virus, etc. (Scholthof et al. 2011). Viruses of microbes infect unicellular prokaryotes (bacteria) and eukaryotes (algae and protozoa) (Debarbieux et al. 2017). Bacteriophages are the commonly studied viruses affecting microbes.

Viruses have been classified (Table 1) depending on factors including virion morphology – type of symmetry, presence or absence of envelop, viral genome – (nucleic acid type and strandedness, sense (positive/ negative), linear or circular, segmented or unsegmented), host range, mode of transmission, etc. (Brooks 2010).

Replication

The first step in viral replication is **attachment**, where the viral attachment proteins (ligand) bind to specific receptor on the host cell plasma membrane (e.g., gp 120 of HIV binds to CD4 of T-helper cells, EBV binds to CD21 on B-lymphocytes). It is followed by **penetration** of the viral nucleocapsid into the host cell, by different mechanisms. In some enveloped viruses, lipid envelop fuses with host cell membrane by help of viral proteins, e.g., gp41 of HIV, F (fusion)

Virus, Fig. 1 Icosahedral symmetry (e.g., Human herpes virus)

Virus, Fig. 2 Helical symmetry (e.g., Tobacco mosaic virus)

Virus, Table 1 DNA and RNA viruses with health implications in humans

Virus families	Symmetry	Genetic material	Envelop	Example of viruses
DNA viruses				
Parvoviridae	Icosahedral	ssDNA linear	Absent	Parvovirus B19
Papillomaviridae	Icosahedral	dsDNA circular	Absent	HPV
Polyomaviridae	Icosahedral	dsDNA circular	Absent	JC virus, BK virus
Adenoviridae	Icosahedral	dsDNA linear	Absent	Human Adenovirus
Herpesviridae	Icosahedral	dsDNA linear	Present	HSV1, HSV-2, VZV, EBV, CMV, HHV-6, -7, -8
Hepadnaviridae	Icosahedral	dsDNA circular incomplete	Present	Hepatitis B virus
Poxviridae	Asymmetrical (Complex)	dsDNA linear	Present	Variola, Molluscum contagiosum virus
RNA viruses				
Picornaviridae	Icosahedral	ss +ve sense	Absent	Poliovirus, Echovirus, Enterovirus, Coxsackievirus, HAV
Orthomyxoviridae	Helical	ss -ve sense segmented	Present	Influenza virus
Paramyxoviridae	Helical	ss -ve sense	Present	Parainfluenza virus, Measles virus, Mumps virus, Nipah virus
Rhabdoviridae	Helical	ss -ve sense	Present	Rabies virus, Chandipura virus
Togaviridae	Icosahedral	ss +ve sense	Present	Chikungunya virus
Flaviviridae	Icosahedral	ss +ve sense	Present	Japanese B Encephalitic virus, Dengue, Yellow fever virus
Caliciviridae	Helical	ss +ve sense	Absent	Norwalk virus
Arenaviridae	Helical	ss -ve sense segmented	Present	Lassa virus, Lymphocytic choriomeningitic virus
Bunyaviridae	Helical	ss -ve sense segmented	Present	Hanta virus, Sandfly fever virus, Ganjam virus
Filoviridae	Helical	ss -ve sense	Present	Ebola virus, Marburg virus
Reoviridae	Icosahedral	ds segmented	Absent	Reovirus, Rotavirus
Retroviridae	Icosahedral	ss +ve sense (2 copies)	Present	HIV, HLV

Abbreviations: *HPV* Human papilloma virus, *HSV* Herpes simplex virus, *VZV* Varicella zoster virus, *EBV* Epstein barr virus, *CMV* Cytomegalovirus, *HHV* Human herpes virus, *HAV* Hepatitis A virus, *HIV* Human immunodeficiency virus, *HTLV* Human T-cell lymphocytotropic virus

glycoprotein of paramyxovirus. Other viruses (e.g. influenza virus), are taken inside an endosome by clathrin coated pits. Viral envelop and endosome membrane fuse afterwards. **Uncoating** of the viral nucleic acid then occurs, due to dissolution of viral capsid by the host enzymes.

The viral nucleic acid then transcribes mRNA followed by synthesis of early proteins (that shut the host genetic machinery). Viral genomic replication follows and progeny genome causes late mRNA transcription leading to synthesis of viral structural proteins. The structural components of virus assemble to form virions, which are then released from host cell.

Generally viral proteins are synthesized in the host cytoplasm using host ribosomes and viral mRNA, viral genomic RNA replicates in host cytoplasm, and viral genomic DNA is replicated in host nucleus. There are, however, few exceptions (Brooks 2010). Figure 3 shows the strategies adopted by different class of viruses for replication and protein synthesis.

Immunity Against Virus

Both innate and adaptive immune systems operate against viral infection. The macrophages and dendritic cells engulf the virion and serve as antigen presenting cells (present antigen to T-helper lymphocytes) and also produce variety of cytokines for activation of adaptive immune cells. Viruses downregulate MHC I (Major Histocompatibility Complex – class I) expression by the infected cells. Such cells are targeted by Natural killer cells (NK cells) which produce perforins and granzymes to cause target cell apoptosis. NK cells also produce IFN γ and TNF α (tumor necrosis factor α) which are essential for combating viral infection. Type 1 Interferons (IFN α , IFN β) are produced by virus infected cells and plasmotoid dendritic cells (even when not infected). Type 1 IFNs upregulates expression of antiviral genes in both infected and uninfected cells. IFN γ also causes activation of macrophages and NK cells.

Antibodies, produced by helper T-cells (CD4+) and B-cells can neutralize the viral attachment

proteins. Complements also have neutralization action. Cytotoxic T cells (CD8+) play major role in controlling infection as they kill the virus infected cells (Delves et al. 2017; White et al. 1994).

Evolution of Virus, Mutations, and Consequences

Different theories for origin of viruses have been proposed. Viruses may have originated from the genome of host cells or by degeneration of infecting intracellular parasites. DNA and RNA viruses have probably originated from different sources as they vary profoundly (Brooks 2010). The characteristic features of viruses of microbes are different from those of humans and other animals; however, evidences support that they evolved from the same source (Bamford et al. 2005).

Viruses keep evolving for fitness, i.e., “*ability of the virus to replicate infectious progeny*” (Domingo et al. 1996). Viruses have evolved to evade (escape) host immune system (Male et al. 2012) by various strategies like-

- Avoid being recognized by mechanisms like latency, infecting immunologically privileged sites
- Downregulate MHC I and MHC II as seen in HIV infection
- Change antigens by drift and shift as seen in influenza virus
- Affect antigen processing as seen in CMV infection

The RNA viruses are able to breach the boundary of species and capable of infecting new hosts. High mutation rates make them capable of evolving at a faster rate (Holmes 2009). Influenza virus has evolved by re-assortment (mixing of genetic material of one human, one bird, and two swine strains). This has altered its virulence, making it capable to develop a pandemic (Taubenberger and Kash 2010). The recent finding shows that HTLV-1 can cover itself in a carbohydrate-rich adhesive extracellular “cocoon,” similar to bacterial biofilms.

Virus, Fig. 3 shows the strategies of replication and protein synthesis used by different types of viruses: (1) in most dsDNA viruses (e.g., Herpesvirus, Adenovirus), viral DNA transcribes mRNA by the help of enzyme DNA-dependent RNA polymerase (RNA polymerase-II of host), mRNA translates early viral protein in the cytoplasm. DNA replication occurs with the help of host DNA polymerase in the nucleus. In poxvirus, the mRNA transcription and genomic replication occurs in cytoplasm because the virus carries its own DNA and RNA polymerases (2) In Parvovirus ssDNA of virus is first converted to dsDNA by cellular DNA polymerase, then mRNA transcription occurs. (3) In dsRNA containing viruses (e.g., Reovirus), each virion carries RNA-dependent RNA polymerases which use each strand to transcribe mRNA (4) In ssRNA viruses of positive sense, the RNA directly can act as mRNA transcript, genomic RNA is replicated via a negative sense RNA intermediate. (5) Viruses (e.g., influenza virus, rhabdoviruses) with negative sense RNA

viruses carry RNA polymerases for mRNA transcription. (6) Retroviruses (e.g., HIV) have reverse transcriptase enzyme which transcribes DNA strand using each of the viral ssRNA strands (RNA-dependent DNA polymerase activity), it then lyses the parent ssRNA (ribonuclease activity) and forms complementary DNA strand taking the newly formed ssDNA as template, ultimately resulting in the dsDNA which then enters the host nucleus and binds to host DNA with the help of enzyme integrase. When the cell is actively replicating, viral mRNA is transcribed and protein synthesis occurs. (7) In Hepatitis B virus, which has partially dsDNA (circular -not shown in figure), the viral genome is first converted into covalently closed circular dsDNA (cccDNA), which serves as template for mRNA transcription, pre-genomic positive sense RNA is produced too which with the help of reverse transcriptase enzyme subsequently form the genomic partially dsDNA (not shown)

This novel mechanism of viral transmission ensures the efficient and protected viral transfer between cells (Thoulouze and Alcover 2011).

During evolution, changes in the viral genetics occur by means of mutation and recombination, which may alter the virulence power of the virus. An avirulent virus may turn virulent or a less virulent virus may become highly virulent. This leads to newly emerging diseases (Domingo et al. 1996; Roossinck 1997; Morse and Schluederberg 1990). Environmental changes (e.g., Global warming, ecological changes, demographic changes, migration) do play a role in activation or mutation in the viruses and may result in these emerging viral infections (Morse and

Schluederberg 1990; Olival and Daszak 2005). The common emerging viral infections are those caused by – Nipah virus, paramyxoviridae, zika, and ebola viruses (Bishop 2015; Olival and Daszak 2005; Wikan and Smith 2016).

Health Implications

Viruses can cause several diseases in humans (Table 2). Parvovirus B19 can have dangerous manifestation like aplastic anemia and carditis. Hemorrhagic fevers manifest as widespread bleeding from epithelial surfaces. Different hepatitis viruses are grouped under different families and

Virus, Table 2 Important groups of viral infections in humans

Disease groups	Important causative viruses
Viral exanthems	Measles, Rubella, Mumps, Varicella viruses
Arthralgia and arthritis	Chikungunya, HBV, HIV, Zika viruses
Hemorrhagic fevers	Yellow fever, Dengue, Ebolavirus and Marburg viruses
Viral gastroenteritis	Rotavirus (common in childhood), caliciviruses, enteric adenoviruses
Hepatitis	Hepatitis viruses (A, B, C, D, E), yellow fever virus, HSV, EBV, CMV
Genitourinary infection	HSV-2, HPV- 6, HPV-11
Oncogenic viruses	HPV types 16 and 18, HBV, HCV, EBV, polyoma virus, HHV8, HIV, HTLV
Cardiitis	Coxsackie B viruses, adenovirus, parvovirus B19
Encephalitis	Japanese B encephalitis; Eastern, Western, and Venezuelan encephalitis; Herpesviridae family; Picornaviridae family; and Adenovirus
Respiratory infections	RSV, adenovirus, SARS-CoV MERS-CoV, Influenza, and Parainfluenza virus

SARS CoV Severe acute respiratory syndrome, *MERS CoV* Middle east respiratory syndrome

differ greatly in pathogenicity. Cancers that can be caused by viral infection include cervical cancer by HPV 16 and 18, hepatocellular carcinoma by HBV & HCV, Burkitt's lymphoma and nasopharyngeal carcinoma by EBV, lymphomas by HIV virus, Kaposi Sarcoma by HHV8, and leukemias by HTLV. SARS & MERS have rapidly affected many people (reaching close to a pandemic) in recent past. H1N1 flu is the recent most pandemic infection caused by re-assorted influenza virus and is still continuing in India. Zika virus infection in the pregnant female may lead to microcephaly in the new-born child and Guillain- Barré syndrome in adults (White et al. 1994).

In-utero exposure to viruses has been hypothesized to increase the risk of development of schizophrenia, bipolar disorder, autism, and mental retardation in the child (Chess et al. 1978). Viral infection involving the central nervous

system may present with psychiatric manifestations (psychosis, catatonia, mania, and depression) (Freudenreich et al. 2011). Viral infections like HIV, HSV can involve brain and produce cognitive deficits (Dickerson et al. 2004). Serious viral infections (HBV, HCV, and HIV) have been reported in patients with severe mental illnesses. Risky behavior and altered immune status in these patients might be responsible for such coinfections (Klinkenberg et al. 2003).

Certain viruses may remain latent in certain part of the body, after primary attack. JC virus, for example, commonly has subclinical or very mild manifestation in primary attack, and goes unnoticed. However, it remains latent in kidney and brain, and is a frequent cause of progressive multifocal leukoencephalopathy after renal transplantation. Subacute Sclerosing Panencephalitis (SSPE) is a late sequel of measles, though its occurrence has reduced due to vaccination (Garg et al. 2019). Mutated viral genome has been isolated from the brains of patients with SSPE. SSPE often has onset in the adolescence and manifest with cognitive impairment, myoclonus, ataxia, and visual disturbances (Garg et al. 2019).

Laboratory Diagnosis

Samples like swabs (from throat, eye, and skin lesions), feces, CSF from suspected viral cases should be properly collected and transported in viral transport medium (VTM). Collection of the sample from the appropriate site during the course of disease is very critical for direct detection of virus.

Direct demonstration of the virus can be done under electron microscope. Detection of viral antigens can be done by ELISA, Latex agglutination, Immunofluorescence, and Immunochromatography can done depending upon the available formats. Viral nucleic acid can be detected by PCR, Microarray, and other molecular techniques. They are generally the most sensitive and rapid methods for diagnosis. Viral isolation is considered "gold standard," but the isolation of virus in cell lines (e.g., Vero cell line), animal inoculation, and egg inoculation are costly and time consuming and used mainly for research purpose (White et al. 1994).

Detection of antibodies against the viral antigens in the patient blood by ELISA are frequently used screening tools for detection of viral infections. A raised specific-IgM indicates recent infection, whereas, a raised specific IgG can detect past infection. A lot of viral diseases like JE, Dengue, Chikungunya, and Zika are diagnosed by detecting antibodies against them in the patient serum. They are also very sensitive and commonly employed tests.

Advantages of Viruses

Certain vaccines are produced by the live attenuated strains of the viruses, which protects the individual from the infection by the virulent strains of similar viruses. Bio-engineering has used viruses for carrying and protecting genomic information (Li et al. 2010). Viruses can transfer genetic material to their host (e.g., Bacteriophages), which integrates with the host genome, thereby facilitates the evolution of organisms (Roossinck 2011). An important example is evolution of antibiotic resistant bacteria. Many viruses have symbiotic relationships with their hosts and protect the host (Roossinck 2011).

Conclusion

Viruses have abundant health implications including – cancer, neurological, and psychological implications. Viruses continuously interact with the environment and their host, through which they evolve. Prevention of the serious health conditions need development of new and effective vaccines against viruses. There is a lot of scope for research in this field.

Definition

The mechanism whereby individuals tend to remain near their place of birth and which leads to high genetic relatedness among neighbors.

Introduction

Population viscosity occurs whenever individuals tend to remain near their place of birth, a process that generates high levels of relatedness among neighbors, which is a key factor to kin selection (Hamilton 1964). Kin discrimination allows individuals to discriminate genealogical relatives and to direct altruism toward them (Hamilton 1964). The greenbeard effect allows individuals to discriminate genetic relatives, irrespective of their genealogical ancestry, in which individuals express a phenotypic trait (i.e., the greenbeard) that they recognize in other individuals so that they are able to direct altruism toward them (Hamilton 1964; Dawkins 1976). Because population viscosity does not require any sophisticated recognition mechanism, it is thought to be a general and important relatedness-generating mechanism (Hamilton 1964). In addition, because neighbors are likely to be relatives, population viscosity may even allow for the evolution of indiscriminate altruism (Hamilton 1964).

Population viscosity, however, also poses some challenges for the evolution of altruism. Hamilton pointed out that when the young remain close to their place of birth, they are more likely to compete against each other for local resources (Hamilton 1964). Despite this, Hamilton thought that kin competition would not be sufficiently strong to cancel out the benefits generated by population viscosity, a view that was later challenged by Alexander (1974). Following these verbal arguments, Bulmer (1986) developed a theoretical model to test the effect of population viscosity on the evolution of sex allocation, a social trait in viscous populations. In his model, he showed that the relatedness-enhancing effects and the competition-enhancing effects of population viscosity exactly cancel each other out, so that sex allocation is independent of population viscosity. Taylor (1992) developed an analytical model that specifically focused on the evolution of a public good trait and also arrived at an invariance result, in which altruism is not influenced by the degree of population viscosity.

Bulmer and Taylor's models have motivated a large theoretical and empirical literature on the

evolution of social traits in viscous populations. Theoretical models, for instance, have analyzed how different ecological, demographic, and genetic factors may influence the population viscosity invariance result (reviewed by Lehmann and Rousset 2011). Empirical studies have investigated the importance of kin competition in the evolution of social traits and the relationship between relatedness and social evolution (e.g., West et al. 2001; Griffin et al. 2004; Kümmerli et al. 2009; Wu et al. 2015).

Altruism in Viscous Populations

Bulmer (1986) was the first to provide a mathematical treatment of the evolution of a social behavior and to attest the strength of kin competition in viscous populations by focusing on the evolution of sex allocation, a social trait in viscous populations. The basic setup of Bulmer's model assumes that a mother breeds solitarily, and mating occurs among her own offspring before her daughters disperse away to breed elsewhere. Under this scenario, a mother has an incentive to produce a large number of daughters, but only a small number of sons, just enough to ensure fertilization of all her daughters (Hamilton 1967). This extreme female-biased sex ratio minimizes wasteful competition for mates among her sons and maximizes her number of grandchildren. By contrast, if a mother breeds alongside unrelated females, her sons face competition from unrelated males. Competition among unrelated males favors mothers who produce more sons, which results in relatively less female-biased sex ratios.

Competition, however, need not occur among unrelated males. If some females remain near their place of birth, mothers within each social group are likely to share a recent common ancestor. As a result, young males tend to compete for mates with collateral kin, rather than unrelated males, raising the hypothesis that population viscosity promotes the evolution of extreme female-biased sex ratios; Bulmer (1986) set out to test this hypothesis. His model, however, did not support this prediction. Surprisingly, he showed that the sex ratio does not change with population

viscosity. Relatedness does increase with population viscosity, which favors mothers who have fewer sons (and more daughters). However, population viscosity also increases competition for local resources among related females, which favors mothers who have fewer daughters (and more sons). These two opposing forces exactly cancel each other out so that population viscosity has no net impact on the evolution of the sex ratio (see Box A for details).

Box A

Let us consider a diploid sexually reproducing population subdivided into a very large number of patches, each with a high-fecundity (H) and a low-fecundity mother (L) with fecundity F_H and F_L , respectively (Rodrigues and Gardner 2015). High-fecundity (or low-fecundity) mothers produce a fraction z_H (or z_L) of sons and a fraction $1-z_H$ (or $1-z_L$) of daughters. After reproduction, newborn female and male offspring mate. After mating males die, a fraction d of the mated females disperse away to a random patch in the population, while a fraction $1-d$ remain in the local patch. After dispersal, native and migrant females compete for the two available breeding sites. We are interested in the optimal sex allocation strategy of each breeding mother. A mother should invest slightly more into sons if

$$\begin{aligned} & c_m \frac{1}{n_m} r_S - c_f \frac{1}{n_f} r_D \\ & - c_m \left(\frac{1}{n_f} + \frac{1}{n_m} \right) r_{iM} \\ & + \frac{1}{n_f} \varphi(c_f r_{iF} + c_m r_{iM}) \\ & > 0 \end{aligned} \quad (A1)$$

where c_f (or c_m) is the class reproductive value of females (or males); r_D (or r_S) is the relatedness between mothers and daughters (or sons), n_f (or n_m) is the proportion of

(continued)

daughters (or sons) in the population, r_{iF} (or r_{iM}) is the average relatedness between a mother of quality “i” and female offspring (or male offspring), and φ is the probability that two female offspring remain in their native patch. The first term represents the value of sons, while the second term represents the value of daughters. The third term represents the competition for mates among males, while the fourth term represents the competition for resources among females. Population viscosity increases the relatedness between a focal mother and male offspring born within the patch (i.e., r_{iM}), and therefore a mother is favored to invest less into sons. However, population viscosity also increases competition for resources among female offspring (i.e., φ , r_{iF} and r_{iM}), and therefore a mother is selected to invest less into daughters. When the quality of the two mothers in the patch is identical (i.e., $F_H = F_L$), these two opposing forces exactly cancel each other out so that population viscosity has no net impact upon the evolution of the sex ratio. In other words, the optimal sex allocation strategy in a well-mixed population (i.e., $\varphi = 0$) and in a viscous population (i.e., $\varphi < 0$) is exactly the same (Bulmer 1985). However, when the quality of the two mothers differs (i.e., $F_H > F_L$), then population viscosity does have an impact upon the evolution of the sex ratio. In a viscous population, high-quality mothers are now selected to invest more into sons than low-quality mothers (Rodrigues and Gardner 2015).

Taylor (1992) also treated the problem of the evolution of social traits in viscous populations. However, he explicitly focused on a public goods game model, in which individuals provide a benefit to everybody in the group at a cost to themselves and in which he was able to provide an analytical treatment of the problem. Like Bulmer, he arrived at an invariance result, in which the level of investment into the public good does not

vary with population viscosity. Again, the cooperation-enhancing effects of population viscosity are fully cancelled out by the cooperation-inhibiting effects of population viscosity (see Box B for details).

Box B

Let us assume an asexual and haploid population subdivided into an infinite number of groups of n individuals. Each individual produces a very large number F of offspring and dies afterward. Each offspring disperses with probability d to a random patch in the population and remains in the local patch with probability $1-d$. Both migrant and native individuals then compete for the n available breeding sites in each patch. After competition for breeding sites, offspring become full reproductive adults, which bring the life cycle of our model species to its beginning. To determine the direction of selection, we take the neighbor-modulated approach to kin selection (Hamilton 1964; Taylor and Frank 1996). We focus on the evolution of a cooperative trait that costs C offspring to its bearer but provides B additional offspring to a bearer's social partners. The level of expression of this trait in a focal individual is x , the level of expression of the trait in the focal individual's social partners is y , and the average expression of the trait in the population is z . The neighbor-modulated fitness of a focal breeding adult is then given by

$$w = F(x, y) \times \left(\frac{(1-d)}{F(y, y)(1-d) + dF(z, z)} + \frac{d}{(1-d)F(z, z) + dF(z, z)} \right) \quad (\text{B1})$$

The selection gradient is given by the slope of fitness on the phenotype of the focal individual, which is $dw/dx = \partial w/\partial x + \partial w/\partial y \cdot r$, where r is the coefficient of relatedness between interacting partners. Expanding this equation we get a form of Hamilton's

(continued)

rule, the condition for the evolution of the altruistic behavior, which is given by

$$-C + Br - (B - C)hR > 0 \quad (\text{B2})$$

where $h = (1-d)^2$ is the probability that one of the additional offspring generated by altruism remains in the local patch and destroys a native offspring. Altruism creates B additional offspring, who are related to the actor by r , but it also destroys $(B-C)h$ local offspring, whose value to the actor is R . Because of $r = hR$, the kin competition effect completely negates the kin-selected benefits of population viscosity (Taylor 1992).

Bulmer and Taylor's models are extremely important because they provide a social evolution invariance result – the level of cooperation does not change with population viscosity – against which other hypotheses can be contrasted. Because Bulmer and Taylor's models lack many of the life history and ecological variables observed in natural populations, they have motivated a wealth of theoretical and empirical studies investigating how these different factors influence the evolution of social traits in viscous populations and whether they breakdown the invariance result (Lehmann and Rousset 2010; see Box A for an example).

An empirical test of the role of population viscosity comes from a study on the bacterium *Pseudomonas aeruginosa* (Griffin et al. 2004; Kümmerli et al. 2009). *P. aeruginosa* is a bacterium that requires iron for fundamental metabolic functioning. However, most of the iron available in the environment comes in the Fe(III) form that is not readily metabolized by this bacterium. *P. aeruginosa* can overcome this problem, however, by producing and secreting molecules called siderophores that bind to Fe(III) making it edible for the bacterium. A problem with this system, however, is that the manufacturer of a molecule might not benefit from its end product, and therefore bacteria that do not pay the metabolic cost of

molecule manufacture but that benefit from its production may gain a fitness advantage. Researchers are therefore interested in understanding what are the mechanisms that stabilize cooperation in *P. aeruginosa*. Experimental evolution has shown that population viscosity might stabilize cooperation in *P. aeruginosa* (Griffin et al. 2004). By varying both the number of clones that started a new colony and whether the different clones were allowed to compete with the global population or not, they found that siderophore production was more likely to evolve when relatedness is high and kin competition is low.

Class Structure in Viscous Populations

Most of the studies of the problem of altruism in viscous populations have been focused on cases in which quality does not vary among individuals (e.g., Bulmer 1986; Taylor 1992). Recent work, however, has begun to analyze how individual quality influences the evolution of altruism in viscous populations (e.g., Rodrigues and Gardner 2013, 2015). In natural populations, not all differences among individuals are due to their genetic makeup, and in many cases, differences among individuals emerge due to non-genetic factors such as age, reproductive state, size, nutritional state, or sex. Variation in individual quality introduces class structure in a population, where the change in gene frequency over one generation may not be representative of long-term adaptive changes in gene frequency. For instance, over one generation a mother who produces a single high-quality offspring loses out the (short-term) evolutionary race to a mother who produces multiple low-quality offspring. However, if we consider the change in gene frequency over several generations, the mother who produces a single high-quality offspring may well win the long-term evolutionary race. As adaptive evolution concerns long-term gene frequency change, the solution to this problem is to weigh the value of each offspring by their long-term contribution to the gene pool of future populations (i.e., their reproductive value), instead of considering solely

the number of offspring as a measure of fitness (e.g., Rodrigues and Gardner 2013).

In some cases, the quality of the young varies, and some are condemned to have lower fecundity than their more fortunate siblings. Rodrigues and Gardner (2013) set out to study how variation in quality among social partners influences the evolution of altruism in viscous populations. They found that Hamilton's rule, the condition for the evolution of a social behavior, is given by

$$-Cv_A + Brv_R - (B - C)hvr_S > 0, \quad (1)$$

where v_A is the reproductive value of the actor, r is the relatedness between the actor and the recipient, v_R is the reproductive value of the recipient, h is the probability the extra offspring generated by altruism remain in the local patch and that they take up resources of other native offspring, v is the reproductive value of philopatric offspring, and r_S is the relatedness between the actor and those offspring who suffer additional competition owing to the extra competition for resources. First, they found that individual variation among group members breaks down the cancellation result of Bulmer and Taylor so that viscosity influences the level of investment into cooperation. Second, they found that low-quality individuals invest more into altruism, while high-quality individuals invest more into selfishness. Finally, as the population becomes more viscous, low-quality offspring are favored to sacrifice their lives in favor of their more fortunate high-quality relatives.

Kin Competition

An offshoot of the study of social traits in viscous population was the renewed interest in the role of kin competition in the evolution of social behavior. Kin competition is prevalent in the natural world and often mediates selfish and spiteful traits among related individuals. In the simplest theoretical models, kin competition exactly cancels out the benefits of population viscosity, as we have seen above. In the natural world, however, these two opposing forces vary considerably and

are influenced by the different ecological, demographic, and genetic variables as well as the life cycle of the species.

A remarkable example of how kin competition influences the evolution of social traits occurs in wasps, where the level of aggression across different wasp species varies widely (West et al. 2001). In some wasp species, adult females lay eggs within figs, with female and male larvae developing inside these figs. Males are wingless and mating occurs within each fig before females fly away to lay their own eggs elsewhere. The average level of relatedness within each fig varies between species, and therefore it is possible to test whether there is a negative correlation between levels of male aggression and relatedness, as predicted by Hamilton's rule. Using a comparative analysis approach, it has been shown that there is no correlation between relatedness and the average level of aggression within each fig (West et al. 2001). By contrast, there is a negative correlation between aggression and the density of available females within each fig, which suggests that the level of aggression is driven by kin competition rather than relatedness. In species where there are fewer available females, males fight more for mating opportunities than in species where females are abundant, irrespective of their relatedness.

Kin competition also seems to play a role in the social behavior of humans. Wu et al. (2015) found that the level of female and male dispersal (or viscosity) influences the tendency to cooperate in Southwest China villages. The level of female dispersal varies between different villages. While in some villages both women and men remain close to their place of birth, in other villages women show an intermediate level of dispersal, with some women remaining in their native village, but others moving to different villages. When both women and men remain in their villages, average relatedness goes up within each village. Surprisingly, researchers found that in such cases the level of cooperation drops and individuals are less likely to cooperate when playing economic games. When some of the women disperse to a different village, relatedness is relatively lower. However, they found that in

such cases individuals are more likely to cooperate. These two examples highlight the general idea that cooperation depends on the fine balance between the cooperation-enhancing and the cooperation-inhibiting forces of population viscosity.

Conclusion

Population viscosity occurs whenever individuals tend to remain near their place of birth. Alongside kin discrimination and the greenbeard effect, population viscosity is one of the main mechanisms capable of generating relatedness among social partners, which allows kin selection to operate. In a viscous population, neighbors are likely to be relatives, and therefore population viscosity may even allow for indiscriminate altruism, unlike kin discrimination and the greenbeard effect. Moreover, because it does not require any sophisticated recognition mechanism, it is thought to provide an important and general solution for the problem of altruism. Population viscosity, however, also leads to kin competition, which may slow down, and in some cases even impede, the evolution of altruism.

Definition

The conservation and adaptation of primordial visual substrates throughout the phylogenetic tree to humans.

Introduction

The topic of evolution is more than an academic discipline that serves to simply annotate our ancestral past. Gaining knowledge into how

structure relates to function and how that interplay was shaped by the selective pressures over an array of changing environments bolsters our ability to understand mechanisms of action and to defend ourselves against disease. Few organ systems permit the level of accessibility that the eye provides, both anatomically and through evolutionary conservation, to test and evaluate the driving forces of evolution (reviewed in Caves et al. 2018). The visual system transcends 550 million years of protozoan and animal phylogeny, is highly accessible due to the extracranial origin in many animals, and benefits from a vast interdisciplinary knowledge of the genetics and epigenetic factors that regulate its development and function. Exploiting these attributes allows us to further understand the evolutionary origin of human disease genes and greatly widens our toolkit from which we can modify and engineer treatments to combat blinding ailments (Domazet-Lošo and Tautz 2008). By extension, exploiting what we learn about early protovisual substrates, such as the discovery and reengineering of channel rhodopsins (Berthold et al. 2008; Ernst et al. 2008), endows us with the potential to modify or enhance our visual system through therapeutic intervention (Deisseroth 2011). For these reasons, the visual system has greatly informed the wider field of evolution.

The Blueprint of Vision

The human visual system is composed of an eye which functions to capture and sense light, process that information through early neural processing, and send this information through physical projections to the brain via the optic nerve tracts (reviewed in Dowling 1999). The beginning of the visual cascade is the transduction of light photon energy into a biochemical and neural signal. This initial process takes place in rod and cone photoreceptors located in the outer nuclear layer, which send their information to a series of interneurons located in the inner nuclear layer. Lateral processing at this level provides pre-processing of neural signaling which generates a coded visual output to retinal ganglion cells.

These 3rd-order neurons then project to several structures within the brain to be integrated into higher processing of sensation and perceptive functions. Input from this light-sensitive system regulates aspects of circadian entrainment, vision, and higher executive functions that process sensory information. Ultimately, this structural arrangement, comprised of a photon sensor, a local processor circuit, and neural projections to brain regions that control higher functions, underlies the basic architectural blueprint of not only the mammalian visual system but lower animals as well (reviewed in Gehring 2014). At its origin, this blueprint evolved from the simplest of visual architectures. Our protozoan ancestors established strategies to orient themselves in relation to energizing light stimuli. Moving toward light energy for the positive benefit of energy production (phototaxis) and moving away from intense light to protect themselves from photo-damage (negative phototaxis) imparted a survival advantage. This progression required two important structural and biochemical adaptations: one, the ability to transduce light energy into a cellular signal that is in some way coupled to organism motility machinery, such as cilium or flagella, and two, some degree of anatomical asymmetry that can be used to interpret the direction of a light source. As previously described by Nilsson and colleagues, these behavioral adaptations emerged from a sequence of physical adaptations that include organ asymmetry, assimilation of light-absorbing pigments, constriction of the organ to aperturate the light path, and the development of a lens to compensate for limited light capture (Nilsson 2009). Protozoa, which bridge the gap between plants and animals, evolved a functional photoreceptor capped with a photon-absorbing carotenoid pigment complex (reviewed in Williams 2016). These two structures collectively provide light sensitivity, protection from photo-damage, and the selective ability to block photo-detection from one direction. Although this ancestral-prototype visual complex has evolved in many forms, the strategy of controlling the path of light in relation to a phototransduction element forms the basis of vision systems in higher organisms.

Lower Organisms to Humans

The many ontogenic steps that occupy the evolutionary tree of vision between early prokaryotes and humans provide us with insight into adaptations to this architectural blueprint (Williams 2016). Simple visual systems present in organisms such as filamentous bacteria elaborated the basic photoreceptive effector to influence motors, such as motile cilia. This adaptation of light-guided motility was achieved via the recruitment of molecular signaling pathways (Lamb et al. 2009). This basic visual framework is evident throughout many taxa to human photoreceptors, which exhibit an evolutionarily conserved common domain occupied by ancestrally related photopigments within the primary cilium. The compound eye of the *Drosophila* fly also utilizes a distinct architectural array of individual photoreceptive units termed ommatidium, rather than a laterally convergent retinal circuit that is evident in most vertebrates. These compound-style eyes contain numerous columns of individual lenses and photoreceptors that more directly synapse onto projection neurons in the fly brain (Kumar 2018). Vertebrate eyes, in contrast, utilize a single “camera-style” lens to focus light onto the entire retina and employ multiple lateral processing interneurons to achieve preprocessing ahead of 3rd-order retinal ganglion cells. In part due to this diversity in how organisms exploit and deploy the basic blueprint of photoreception, research into visual system evolution has greatly elaborated our understanding of the mechanisms that mediate organism diversity. The genetic encoding of eye development offers a similar analogue from which we can interpret evolutionary progression (Lamb 2013). The highly conserved paired-type homeodomain gene *Pax6*, as an example, regulates the earliest specification of the eye primordium during development (Pichaud and Desplan 2002). The role of the *Pax6* gene in driving photosensation is also evident as early as 550 million years ago, making it one of the oldest genes known to regulate eye specification. During this period, atmospheric oxygen and protection from mutagenic photodamage were effectively absent, and *Pax6* had already evolved (Quiring

et al. 1994). As the ocean’s photosynthetic organisms, such as plankton, generated atmospheric oxygen as a by-product, the attenuated impact on light energy permitted a condition in which light could play a role as a substrate for behavioral modifications rather than simply energy production. Genes such as *Pax6* could then be adapted to regulate emerging features of the evolving eye in relation to this changing light environment (Gehring and Ikeo 1999). By 530 million years ago, speciation evolved rapidly from basic photosynthetic organisms to those who adapted camouflage and sexually attractive chromatic elements within their body architecture (Cuthill et al. 2017). It is thought that these adaptations were, in part, driven by *Pax6*, the evolving photoreceptive complex and its acquired ability to gather more complex light information from the environment. The explosion in diversity that emerged after the onset of photoreception fueled morphological and molecular diversity across the vast majority of creatures that exist today. This visual evolution progressed as an adaptation to not only evolving colors exhibited by surrounding organisms (Cuthill et al. 2017) but also the movement of life throughout variations of aquatic and atmospheric media (Sivak and Sivak 2018). For example, terrestrial creatures needed to adapt an ocular system that is optimized for the refractive index of light traveling through air and with relatively little attenuation in intensity through the atmosphere. In contrast, aquatic organisms adapt to a much higher refractive index and are further challenged with the water’s influence on light penetration and wavelength selectivity at various depths. The opsins in deep-sea creatures are tuned to transduce in response to blueshifted photons that are capable of penetrating to greater depths in water. In contrast, the mantis shrimp’s ability to express 16 distinct visual pigment genes, the most discovered to date, reflect the expanded composition of wavelengths present in shallower waters (Cronin et al. 2001). The coupled evolution of vision and photopigment diversity therefore allowed organisms to not only efficiently engage in predatory and defensive behaviors, but also enrich sexual selection within the species in the context of their respective habitats.

Molecular and Anatomical Evolution of Vision

Our knowledge of visual system evolution has been acquired most predominantly through the study of specific substrates that function in vision. For example, *opsin* genes, their sequence homology, mutations, and molecular products of those mutations, have been mapped throughout the evolutionary tree (reviewed in Kawamura 2016). In addition, the emergence of new cell types such as interneurons and cellular modification to cells, such as the recruitment of the primary cilium for photon sensing, follows a similar roadmap throughout evolution. The impact of these genes on structural and anatomical evolution requires that they possess genetic encoding that is sensitive to mutagenic influence. For example, the discovery of the highly conserved function of homeodomain transcription factors, such as *Pax6*, *Vsx2*, *Rx*, and *Rb*, in specifying cell fate and function across the animal kingdom has catalyzed our knowledge of the molecular and genetic evolution of the retina (Colley and Dowling 2013). Failure of these gene assemblies to function can have profound negative effects on the development of the eye due to the necessary nature of their role. Mutations in the *Vsx2/Chx10* gene, which is conserved from *C. elegans* to humans, result in a small eye phenotype termed microphthalmia (Burmeister et al. 1996). More hypomorphic effects of gene mutation are evident following failure of ciliary genes such as *Cep²⁹⁰* to regulate the development of an opsin-rich outer segment (Valente et al. 2006). These ciliopathic mutants have a fully formed eye but are congenitally blind. Thus, transcriptionally encoded decisions help explain the emergence and diversity of new cell types and cellular modifications, as well as the fidelity of their function in refining vision. Perturbations in these genes are linked to a wide array of developmentally regulated disease states, including cancers, underscoring the fundamental importance of their function.

The gross anatomical adaptations throughout evolution are intimately coupled to the genetic programming that regulates the subtle refinement of visual structures. In vertebrates,

the light-sensing organ is the eye which exhibits many adaptive features of our ancestral design (reviewed in Gehring 2014). Eye lids, directional positioning of the eye via extraocular muscles, the complex optics of the many transparent lenses, and liquid components of the eye, as well as the aperture-like iris, collectively regulate the directionality and magnitude of light energy that reaches the neural photoreceptive arena. The curved shape of the back of the eye further optimizes the ability to capture light from various directions. The summation of these components is the enhanced ability to resolve light intensity and wavelength, thus enhancing the function of photosensitive transduction pathways. Although the human visual system is a remarkable example of adaptive organ function, we hardly represent the pinnacle of all notable functions across the animal kingdom. For example, humans are trichromatic visual animals that rely on short (blue), medium (green), and long (yellow-green) color sensitivity and encoding. This is in contrast to the polychromat mantis shrimp, which can resolve an impressive 16 distinct wavelengths of light (Cronin et al. 2001). Some species of raptors are estimated to have 200x the visual acuity of humans and are able to make far more rapid focal adjustments to track prey (Potier et al. 2016; Potier et al. 2017). These exceptional examples of visual molecular and anatomical evolution reflect the unique environmental demands placed on these creatures relative to humans.

Concluding Remarks

Visual evolution is a discipline that transcends a vast spectrum of academic genres and whose content stretches far beyond what we can discuss in a primer. Although much of this chapter is focused on the emergence of eyes from visual primordia, relatively little is described about the complex process of connectivity with the brain and the development of higher processing as it relates to evolution. Fields such as neural regeneration have made great advancements in characterizing the enhanced ability of non-primate vertebrates such as chickens, frogs, and newts to

regrow damaged visual structures (Alunni and Bally-Cuif 2016). Harnessing the information to understand where we lost this regenerative capacity throughout evolution can help us formulate ways to impart therapeutic variations of regenerative properties. The field of stem cell science has added similar contributions to our understanding of evolution, as we are now able to program and regulate many basic aspects of tissue primordium across multiple species (Kempermann 2015; Lai and Aboobaker 2018). This approach can recapitulate the fundamental process of evolution through mutagenic screening, thus offering insight into the relationship between these events and structural adaption. Finally, merging together the assets that lower organisms have retained throughout evolution with mammalian systems offer potential therapeutic substrates. This is evidenced by the emerging data demonstrating that the misexpression of channelrhodopsin and halorhodopsin in the eye (Colley and Dowling 2013; Polosukhina et al. 2012), brain, spinal cord, muscle, and theoretically any other tissue currently offer avenues for the restoration of organ activity that has been compromised by disease.

Acknowledgments I would like to thank Nicole K. Dean for editorial contributions to this chapter.

Definition

Cortical areas that contain cells sensitive to visual stimuli that lie outside primary visual sensory cortex.

Introduction

Association cortex constitutes areas outside the primary sensory and motor cortex and occupies much of the primate frontal, occipital, parietal, and temporal lobes. Association cortex can be broadly subdivided into *parasensory association cortex*, *frontal association cortex*, and *paralimbic association cortex* (Pandya and Yeterian 1985). *Visual* association cortex reflects those association cortical areas in the occipital, frontal, parietal, and temporal lobes that receive direct or indirect input from primary visual cortex, V1, which is the dominant cortical entry point for incoming visual information relayed through subcortical visual nuclei (chiefly the lateral geniculate nucleus) from the retina. The study of primate cortex using architectonic and neurophysiological techniques has led to the discovery of a vast number of unique cortical areas, and a large number of these areas possess cells that are sensitive to visual stimuli. Coverage of all of these areas is beyond the scope of this article, as is in-depth discussion of the visual cortex in primate species less well-studied than that of the macaque, including humans.

Parasensory Visual Association Cortex

The parasensory visual association cortex occupies much of the occipital, inferotemporal, and posterior parietal lobes. Differences in architectonics and patterns of connectivity support the subdivision of parasensory visual association cortex into *first, second, and third order* visual association cortical areas (Pandya and Yeterian 1985). First order association cortex receives feedforward projections from the primary visual cortex, which is located in and around the calcarine sulcus of the occipital lobe. Second and third order visual association cortical areas receive input from primary visual cortex only indirectly through first and second order visual association cortex, respectively. The cellular layers of visual association cortex become less differentiable, particularly in third order visual association cortical areas, which is thought to index an increase in the degree of abstraction from visual sensory information coded in lower order areas (Pandya and Yeterian 1985).

First Order Visual Association Cortical Areas

First order visual association areas are among the best-studied areas of macaque visual cortical areas. First order visual association cortical areas V2, V3, V3A, V5, and V6 form the “tributaries” of the “Dorsal Stream” of cortico-cortical projections which interconnects the posterior parietal cortex (PPC) with occipital cortex and structural targets in the premotor areas of the frontal cortex. First order visual association cortical areas V2, V3, and V4 form the dominant “tributaries” of the “Ventral Stream” of cortico-cortical projections that interconnects inferotemporal with occipital cortex and structural targets in the medial temporal lobe (MTL), limbic system, and prefrontal cortex.

Second and Third Order Visual Association Cortical Areas

Second order visual association cortex receives visual input through first-order visual association cortical areas, whereas third order visual association cortical areas receive visual input through second order visual association cortex. Second

and third order visual association cortex of the temporal lobe occupies the inferior temporal cortex and the ventrolateral junction of the temporal and occipital lobes. Second order visual association areas comprise temporal lobe areas TEO, which occupies the inferior temporal gyrus of the caudal aspect of ventrolateral temporal lobe, and the posterior aspect of its immediate anterior neighbor, area TE, a third order visual association area which occupies the inferior temporal gyrus up to but excluding the temporal pole (Fig. 1).

Several areas in the posterior parietal cortex (PPC) possess cells that are sensitive to visual stimuli. These areas are found in the convexity of the inferior parietal lobe (IPL), in the cortical areas in and around intraparietal sulcus (IPS), which sits in between the IPL and the superior parietal lobe (SPL), and the caudal-most aspects of the SPL itself. The IPL areas Opt, PG, PGF, and PF are ordered one after the other in a caudal to rostral direction. The IPS is split into posterior, medial, ventral, lateral, and anterior subdivisions. The SPL is subdivided into areas PE, caudal PE (PEc), and PG, which is located on the medial side. Many of these areas possess subpopulations of cells that are sensitive to visual or both visual and somatosensory stimulation, consistent with their role in sensorimotor and spatial processing (e.g., Murata et al. 2000).

Paralimbic Visual Association Cortex

Paralimbic association cortical areas constitute those association cortical areas that are directly connected to structures of the limbic system and includes areas of the orbitofrontal cortex on the ventromedial side of the frontal cortex, the cingulate region, located on the medial side of the brain, area TG, which occupies the temporal pole of inferotemporal cortex, and structures in the perirhinal and parahippocampal region, areas TF, TL, and TH, which occupy the ventromedial aspect of the temporal lobe. Areas TF, TL, and TH are interconnected with the hippocampus via entorhinal cortex. Each of these areas receives visual input from first and second order visual association cortical areas, auditory input from auditory

Visual Association Cortex, Fig. 1 Visual association areas of the left hemisphere depicted from dorso-lateral (left pane) and ventral (right right) viewpoints. Primary visual cortex (V1) reflects the earliest cortical entry point for retinal information. A successive series of visual feedforward projections from V1 branch into the visual dorsal and ventral streams of the parietal and temporal cortex, respectively. Successively darkened areas reflect

the increasing synaptic distance from V1. Note that the areas are schematically demarcated, and the boundaries are often more graded than are depicted here. Furthermore, the frontal visual association areas are not illustrated, and the vast majority of association areas are subdivided functionally and anatomically into finer-grained subregions the details of which are beyond the scope of this entry

association areas, and somatosensory input via the multimodal region of the IPL (Pandya and Yeterian 1985).

Properties and Functions of Visual Association Cortex

Visual association areas integrate stimulus properties extracted from low level information extracted from across the visual field; they integrate information from across other sensory areas and from the motor cortices; and they integrate online input with stored information in memory to construct complex representations of the environment for interpretation, planning, and action.

An increase in the *order* of a visual association area coincides with less cortical magnification, coarser retinotopic organization, and greater

diversity in cellular visual receptive field size. Second and third order areas along the IT and in the PPC possess cells with large receptive fields that include the fovea bilaterally but possess a disproportionately large coverage in the contralateral visual field. These properties make these areas well-suited for integrating information across areas of the visual field. In addition, second and third order areas receive converging inputs from a number of disparate lower-order visual association areas. While these lower order areas generally overlap in the categories of stimulus properties they process, each one will specialize in the processing of one or more visual stimulus features. For example, while V5 is not the only area to process visual motion, it does not process color, whereas V4 is the dominant first-order color processing area, but is not the only area that processes color. Importantly, the responses of many

cells in visual association cortical areas are often highly selective and are driven by more complex visual stimuli or a combination of visual and other sensory or motor modalities (Bullier 2001).

First order visual association areas often respond to more specific properties or stimulus attributes such as the direction of object motion or the shape of objects. As opposed to lesions of primary visual cortex, lesions of first order visual association cortex often spare the detection of low level stimulus properties such as luminance and contour but can produce a deficit in the perception of composite features such as object shape. In humans and in the macaque, lesions to the dominant visual motion processing center, V5 and its surrounding satellite structures, result in a deficit in recognizing the direction and speed at which objects or scenes are moving, referred to as *akinetopsia* (Rudolph and Pasternak 1999; Zihl et al. 1983). Reversible inactivation of V4 in macaques and the ventrolateral area of the occipital-temporal cortex in humans lead to visual form agnosia, which refers to selective deficits in shape discrimination (Girard et al. 2002; Milner et al. 1991).

In contrast to these deficits in perceptual discrimination of object form, lesions to second and third order visual association cortex in the anterior aspect of the temporal lobe in humans can result in deficits in extracting meaning from objects (McCarthy and Warrington 1986). Consistent with a role in memory, the responses of cells in TE, TG, perirhinal, and entorhinal cortex are attenuated upon the second presentation of an otherwise unfamiliar stimuli, even when the subsequent presentation occurs after many intervening stimuli (Fahy et al. 1993). Other neurons in these same areas respond more to unfamiliar than to familiar stimuli, and, in some cells, this preference can last up to 24 h (Fahy et al. 1993). These areas possess populations of *familiarity* neurons and other populations of *recency* neurons; familiarity neurons respond to relative familiarity but not for how far back in time a stimulus was last presented, whereas the responses of recency neurons depend on how recently a stimulus was last presented, but not their relative familiarity (Fahy et al. 1993).

The organization of visual association cortical areas stands in contrast to the organization in primary visual cortex, in which the integration of visual information across the visual fields of cells is unlikely, given that the axons of neurons responding to one location in the visual field would have to span unusually long distances to influence the output of neurons in primary visual cortex that respond to other regions of the visual field (Bullier 2001). Nevertheless, feedback projections from higher-order visual association areas often span more than one order. For example, second order visual association area TEO and the caudal-most aspect of area TE project back to V1 but there is no feedforward projection from V1 to TEO or TE. Since TE is a known recipient of output from memory-associated structures of the MTL, these pathways presumably function to allow stored information to influence the processing of incoming visual information (Bullier 2001).

Conclusion

Visual association cortex encompasses much of the primate cortex and is distinguishable from primary sensory and primary motor cortical areas on the basis of architectonics, laminar organization, patterns of connectivity, and neurophysiology. These same techniques suggest a further subdivision of visual association cortex into first, second, and third order areas. First order areas can be categorized according to their downstream Dorsal and Ventral Stream targets in the PPC and inferotemporal cortex, respectively, and specialize in the processing of particular stimulus properties or features (e.g., form and color in V4) or states (motion in V5). In the inferotemporal cortex, second order and third order visual areas possess populations of cells that specialize in more complex assemblies of stimulus features stimulus properties to specialization in more abstract representations entailing identity and meaning that are geared for memory, planning, and goal-formulation in the service of immediate object-interactive action or long-term scheduling, and the behavioral and social relevance associated

with the stimulus. In the PPC, second and third order visual areas possess subpopulations of cells that respond to the visual, motoric, and/or somatosensory features of movements made by the eyes, limb, or hand during their planning and/or execution, consistent with the PPC's role in the visual and somatosensory guidance of eye and limb-based action (e.g., Murata et al. 2000).

Definition

Illusion is the difference between the perception of a stimulus and the actual stimulus. Illusions are either adaptations or byproducts of differential selection on information processing mechanisms.

Introduction

An illusion is the difference between an observer's perception of a stimulus and the objectively measurable qualities of that stimulus in the real world. Classic examples of illusions include the moon illusion, where the moon looks larger when it is at the horizon than when it is high in the sky (see Fig. 1). Other classic illusions include the Ponzo illusion, where objects located near the convergence of distant, seemingly parallel lines

Visual Illusions, Fig. 1 Illusion examples. The left, center, and right panels illustrate the moon, Ponzo, and vertical-horizontal illusions, respectively

look larger than the same objects located at the near, diverging end of those lines (see Fig. 1). We typically describe phenomena as illusory only when they occur across individuals in a systematic fashion. There is often no clear or meaningful way to distinguish such phenomena from hallucinations, even though the latter is, strictly speaking, the perception of apparently external stimuli without external sensory stimulation.

The Nature of Illusions

The best examples of illusions occur in a way that is within the observer's capacity to perceive accurately. For example, humans tend to overestimate the length of two-dimensional vertical lines, even though we are able to perceive distances accurately in other situations (i.e., the vertical-horizontal illusion, see Fig. 1). The capacity to perceive accurately that which observers systematically perceive otherwise is the hallmark of an illusion. It is likely that we call such differences illusions only in the rare instance that we notice them.

Illusions are common, rather than exceptional, and this high frequency persists across sensory modalities. For example, our ability to discriminate between multiple points of pressure on our skin depends on the area of the body. Sets of tones can appear to rise without end when the top tone is removed and a bottom tone added (i.e., Shepard's tones). The subjective strength of a smell depends

more on the type of smell than the actual amount of odorant molecules in the air. Objects of larger volume will appear heavier than smaller objects of equal weight (i.e., size-weight illusion). In higher cognition, illusions dominate areas such as moral judgment, memory, and evaluation of romantic partners.

Differences between percept and stimulus exist throughout most information processing. Indeed, humans knowingly seek and create illusory experiences. We use artificial sweeteners in order to fulfill our desires for sugar. We watch television, a two-dimensional pattern of light and shadow, in order to mimic social cues that induce joy to the point of laughter and sadness to the point of tears. Illusions are essential features of human experience.

Illusions are not mere inaccuracies. Inaccuracy could result from an inability to process a stimulus, and yet illusions typically fall within the perceptual capacity of the observer. Likewise, true inaccuracy would result in errors in all possible directions, such as over- and under-estimates of a distance, rather than the systematic, directional overestimates that we see in the vertical-horizontal illusion (see Fig. 1). Indeed, a perplexing feature of illusions is that we naively think that we are perceiving something in error because it appears differently than the way that it actually exists in the world. However, error of perception is an uninformed way to consider these phenomena. Such an approach has stymied the investigation of illusions for most of the history of modern science.

Visual illusions are one of the earliest topics in the behavioral sciences. The earliest cross-cultural psychology experiments by Rivers and even the founding of experimental psychology by Wundt included investigations of illusions (Rivers 1905; Wundt, cited by Winslow 1933). Illusions are among the most frequent images in psychology textbooks and publications. They are at the historical and modern core of psychological science. And yet the discovery of many of the most frequent and largest magnitude illusions in human vision did not occur until recently, when we began a broader integration of illusion research with modern evolutionary theory.

Evolved Navigation Theory (Jackson 2005; also this volume) identifies that illusions are likely accurate, not inaccurate, biological processes. The error is that we measure accuracy via sensory processing, rather than evolutionary fitness consequences. Apparent illusory experiences often *accurately* impact fitness.

For example, falling accidents are a primary source of human mortality and injury worldwide (WHO 2016). Further, descent results in falls more often and more severe than ascent (Cohen and Lin 1991; Haslam and Bentley 1999; Svanstrom 1974). Additionally, distance perception is a major determinant of route choice, wherein humans navigate overestimated routes less than routes that appear shorter (Jackson 2013). These conditions led Evolved Navigation Theory scientists to predict that humans faced selection from falling risks, especially on descent, and that this resulted in cognitive adaptations that overestimate vertical distances, especially while standing at the top of them. This is exactly what we find (Jackson 2005; Jackson and Cormack 2007; also this volume). The Descent Illusion consists of overestimating vertical environmental surfaces more while standing at their top than bottom. This phenomenon happens throughout everyday life and is likely the largest known distance illusion in real-world vision, including an 84% overestimate of environmental distances, rather than the 10–15% magnitude of most distance illusions. This is but one such phenomenon predicted from Evolved Navigation Theory.

The Environmental Vertical Illusion consists of overestimating the types of surfaces the navigation of which most likely result in falls (Jackson and Cormack 2008). The Plateau Illusion consists of both over- and underestimates of a variety of surfaces in ways that reflect navigational risks present over evolutionary time (Jackson and Willey 2013). These illusions can be induced by adding evolutionarily relevant navigation risks to surfaces normally estimated accurately (Jackson and Willey 2011) and can be eliminated from surfaces by removing evolved cues to such risks (Jackson and Cormack 2010). These illusions may produce the fear of falling (Jackson 2009). These are among the few illusions that replicate across disparate human populations (Jackson and Gómez de García 2017) and the evolutionary nature of these predictions outline effects across species. All of these phenomena were predicted under Evolved Navigation Theory by considering natural selection, and not accuracy, as the driving force behind the structure of perceptual systems.

There is no evolutionary impetus for perception that is accurate, *per se*. Perceptual mechanisms, just like all other biological structures, must arise as products or byproducts of evolution by natural selection. Those mechanisms that positively influence differential reproduction are the mechanisms that will come to dominate the population. In order for this to happen, there must be sufficient heritable variation in the population and a net selective advantage of the illusion mechanism. Perceptual mechanisms are the product of evolutionary processes that result in apparent accuracy only as a byproduct of selection for mechanisms that ultimately increase fitness. We find perceptual inaccuracy far more often than accuracy precisely because it is the fitness consequences of behaviors that shape their evolution, rather than any impetus for accuracy. This link between natural selection and the structure of perceptual mechanisms provides an essential, but currently unutilized, insight for behavioral scientists: Illusions indicate selection on behavior and cognition.

The amount of information in the environment is effectively infinite. Organisms only process a very narrow range of information that is skewed

towards those things most important to the differential reproduction of that organism's ancestors over evolutionary time. When we see the areas of information that an organism processes, we are looking at the products of selection on information processing in that species' evolutionary history. Illusions provide an especially rich source of knowledge about selection on cognition because they show, not only the information that is most important, but also the way in which the information is important. Illusions often arise in populations where there is variation in a perceptual mechanism, but where there is also directional selection on that perceptual mechanism. This results in skewed perception in subsequent generations. This process produces dummy mechanisms that reflect selection on specific behaviors, but without consciousness of the phenomenon or its causes. This process produces no awareness of broader causes of the illusion, accuracy, or motivational or emotional bias, unless that bias itself was targeted separately by this process. In these ways, an informed evolutionary approach to illusions departs drastically from most other theories of illusions.

Conclusion

In many ways, our understanding of illusions mirrors Darwin's broader realization of evolution by natural selection. Darwin (from Malthus) realized that potential reproduction vastly exceeded actual population sizes, just as we see that the amount of information available in the environment vastly exceeds the amount of information processed by any organism. Similarly, the information that an organism actually processes indicates the specific products of selection, just as Darwin recognized more broadly when looking at the individuals who survive within populations. Illusions are no more coincidental than any other product of selection. Illusions are no more errors than are any other product or byproduct of selection. Understanding illusions in this evolved context has led to the prediction and subsequent discovery of some of the largest illusions. It is this predictive power that identifies evolution by

natural selection as the most important idea in the behavioral sciences.

[Lexicon](#); [Mental lexicon](#)

Definition

Vocabulary is the sum of all words that speakers can use in their speech (productive vocabulary) or comprehend when they are used by other speakers (receptive vocabulary).

Introduction

A child acquiring the lexicon of her language has two main tasks to master: (i) she has to isolate the words in a continuous speech stream and (ii) she has to map the words onto their meanings. First the research on how children segment the speech stream will be introduced, followed by a discussion of how children start assigning meanings to words.

Finding Words in Speech

It is almost impossible to recover word boundaries in fluent speech if one does not already know the words, as anyone who listened to a stretch of talk in an unfamiliar language will agree. But as all normally developing children eventually acquire the vocabulary of their language, it becomes worthwhile to ask how they set about finding words. Acquisition research has so far managed to pinpoint some cues that infants may be relying on to detect word boundaries. In a groundbreaking study, Saffran et al. (1996) have demonstrated that 8-month-old infants can use statistical cues to

extract words from a speech stream consisting of made-up trisyllabic words. This study drew on the simple assumption that the probability with which a syllable follows a given syllable will be always higher word-internally than across a word boundary, e.g., given the syllable *ques*, it is almost certain that the next syllable will be *tion*; but the word *question* can be followed by any arbitrary word, resulting in a low transitional probability for *tion* and the following syllable. In addition, working out the phonotactic constraints of a language (i.e., knowledge of which sound sequences are allowed within a word) can help infants segment the speech stream. For example, the sequence [rpst] can be found within a German word (e.g., *Herbst*, “autumn”), but it will always be separated by a word boundary in English (e.g., *a sharp stick*). Since infants are sensitive to the phonotactic properties of their language by 9 months of age (Jusczyk et al. 1993), they could rely on phonotactics to demarcate the words in a continuous speech stream. Another acoustic cue that speakers use to parse the speech stream is lexical stress. For example, the majority of English words have a *trochaic* stress pattern, i.e., strong syllables are followed by weak syllables (e.g., *AP-ple*), while some other languages such as Turkish exhibit the opposite (*iambic*) pattern (e.g., *el-MA*). Based on this regularity, one could expect English-acquiring infants to observe a metrical segmentation strategy, whereby they assume that all stressed syllables signify a word onset. The current evidence suggests that 8-month-old English-acquiring infants are indeed capable of utilizing lexical stress to extract “words” from a string of artificial language presented to them, even favoring stress cues over statistical cues (Johnson and Jusczyk 2001). This finding might sound contradictory at first, since it suggests that infants use word-level stress as a guide for finding words, but to determine the dominant word-level stress pattern in English, they must have already learned some words. The solution to this puzzle lies in development, as later research has shown that infants first segment the speech by using a domain-general and universally applicable statistical strategy (ca. 7 months of age), gradually transitioning to a stage where they integrate

multiple cues for segmentation (ca. 8 months of age), while giving more weight to sophisticated language-specific cues such as the stress pattern (Thiessen and Saffran 2003).

As a matter of fact, infants should be relying on multiple cues to postulate word boundaries, because none of the strategies introduced above are infallible by themselves. For instance, though most English words are stress-initial, there are exceptions, too (e.g., *be-LIEF*, *sup-PORT*, etc.). Also, computing transitional probabilities may not be effective for detecting English words in a naturalistic setting; since most English words are monosyllabic (unlike the made-up words in the Saffran et al. study) and as such, the syllables will have no *word-internal* transitional probabilities. In fact, Yang (2004) points out that a computational model relying on statistical learning cannot achieve high segmentation accuracy with an English corpus. Accuracy is improved, however, if one postulates a constraint that prescribes that every content word have one primary stress and thereby limits the hypothesis space. So the word-learning task may be facilitated for English-acquiring children if they comply with this constraint as well. These considerations show that successfully parsing a speech stream depends on integrating multiple cues.

Associating Words with Meanings

Once children are able to recognize words in speech, how do they map them onto their meanings? For example, if a young child hears the word *rabbit* in the presence of a rabbit jumping on the lawn, how does she infer that this word refers to the rabbit, and not to parts of the rabbit, to the lawn, or to the action of jumping? Early research on vocabulary development has suggested that children’s word-learning must be constrained by some built-in assumptions about word meanings to help children get their vocabulary off the ground (Markman 1991). One of these is argued to be the *whole-object assumption* that predisposes children to associate novel labels with a whole object, rather than the parts or the substance of that object. But it must be conceded that this

assumption must be abandoned and/or overridden at some point, as children eventually learn the words for object parts and substances. This was arguably made possible by the *mutual-exclusivity assumption*, according to which children would disprefer mapping a novel label onto an object for which they already have a label. Thus, if a child has learned that a rabbit is referred to as *rabbit*, she will be inclined to pick out a different referent for the word *tail*. But the *mutual-exclusivity assumption* is, in fact, at odds with the basic design of the lexicon, since languages do use multiple labels to denote the same entity. Children would thus not be able to learn synonyms or subordinate and superordinate category terms for basic-level terms (e.g., the words *poodle* and *animal*, both of which can denote the same *dog*), if they abided by this assumption.

A more sensible approach to investigating how children build up a vocabulary could be to look at the perceptual and cognitive abilities of children and the social-pragmatic context in which word-learning takes place. The hypothetical scenario where a child has to figure out the referent of the word *rabbit* in the presence of multiple candidates may never play out in a real-life parent-child interaction. Young children are quite adept at establishing joint attention with adults and also reading their communicative intentions by interpreting their gaze direction, affective expressions, etc. Under these circumstances, a child can be expected to easily associate a novel form with the entity that is in her joint locus of attention with her caregiver and this could obviate the need for a *whole-object bias* for determining the referents of labels (Tomasello 2003). Similarly, a *mutual-exclusivity assumption* does not appear to be necessary to explain children's avoidance of lexical overlap. This tendency may stem from a pragmatic *principle of contrast*, according to which every distinct label is assumed to carry a different *meaning* as far as the communicative intentions of the speaker are concerned. Whereas the *mutual-exclusivity assumption* would be hard-pressed to explain how children can produce and comprehend multiple terms denoting a single entity (e.g., *poodle*, *dog*, *animal*), a pragmatically motivated *principle of contrast* would assert that these terms

mark *shifts in perspective* and so they coexist and corefer while preserving the subtle pragmatic differences they signify. Moreover, while *mutual-exclusivity assumption* is formulated as a constraint specific to word-learning, studies show that young children tend to treat not only labels but also facts about objects contrastively; e.g., when children are shown an object and told that "this is from Mexico" and subsequently asked to retrieve the object that "my cat likes to play with," they predominantly avoid choosing the object from Mexico, although the two facts could well be true of the same object. This shows that the pragmatic *principle of contrast* does not solely apply to word-learning, and that it derives from children's ability to reason about which forms a speaker would use to achieve her communicative intentions (Diesendruck and Markson 2001).

It should also be noted that word-learning biases fall short of accounting for the acquisition of verbs, function words, and abstract nouns. The *whole-object assumption* bears no relation to verbs or adpositions – which are more relational than referential. From this perspective, learning abstract nouns (e.g., *love*) or concrete nouns that do not map onto whole objects (e.g., *breakfast*) is also expected to be difficult; though such words are quite common in young children's vocabularies. Needless to say, some version of a pragmatic principle of contrast still needs to play a role in the acquisition of function words and verbs as well; e.g., if an adult uses the verb *share* instead of *have*, this might signal to the child that these words must have different meanings, and eventually enable her to grasp that *share*, unlike *have*, does not involve a claim of ownership, for example (Tomasello 2003). Linguistic context is also crucial for the acquisition of these terms. Verbs differ in the event structures that they instantiate and in the number of participants involved in these events. For example, a transitive verb such as *hit* requires that there be two participants in the event that it denotes (e.g., "*Mary hit Bill*"), while the intransitive verb *sleep* posits one event-participant (e.g., "*Mary slept*"), and research on the acquisition of syntax has provided evidence that 2-year-old children can utilize the number of noun phrase arguments in a sentence to figure out whether the

verb describes a transitive or an intransitive action. This facilitation of vocabulary-learning by the syntax has been dubbed *syntactic bootstrapping*, and it manifests itself not only in the verbal domain. This applies to any argument-taking predicate, including those that contain prepositions, and it has been demonstrated that 2-year-old children can differentiate between made-up homophonous noun phrases (e.g., “*This is a corp!*”) and prepositions (e.g., “*This is a corp my box!*”) by using the sentence structure (see Fisher et al. 2010). While most researchers agree that knowledge of syntax can help word-learning, the traditional syntactic bootstrapping account, which has its roots in generativism, differs from the social-pragmatic view of vocabulary-learning in the role accorded to the syntactic structures in this process. Whereas the syntactic bootstrapping account claims that children are hard-wired to seek correspondences between a verb’s argument structure and its meaning, the social-pragmatic view suggests that children might be first associating the *constructions* they hear with the interactional situation, and segmentations of constructions and abstractions of the meanings of individual words may follow later (Tomasello 2003). For example, a child may hear the sentence “*Joe kicked Mary a ball,*” but the particular argument structure here does not mean that the verb *kick* is a ditransitive verb that describes a transfer event. This semantic component is signaled by the construction *X transfers Y Z*, not by the individual verb. Once this and other constructions have been learned, the child can classify the verb clusters that appear in these constructions and then home in on the individual verb meanings (Goldberg 1995). Unlike the traditional syntactic bootstrapping account, this emergentist view of language acquisition does not require that syntactic structures be a part of children’s innate endowment.

Conclusion

To build up a vocabulary, children need to be able to segment the speech stream into word-sized units, and then associate the words with meanings.

Research has shown that infants are capable of exploiting both the statistical and acoustic properties of speech to accomplish the task of segmentation. Equipped with an inborn capacity to establish joint attention with others and to reason about others’ communicative intentions, infants can then associate words with their referents. Having access to the syntactic structures of their language and the semantic relations they signify will also help children surmount this task; however, the precise syntax-semantics correspondences need not be innate, and children can initially map meanings onto whole constructions and only later partition constructions into smaller word-sized units.

Voice attractiveness

Definition

The desirability of vocalizations to potential mates.

Introduction

Vocalizations across a wide array of taxa exhibit sexually dimorphic acoustic parameters that emerge at sexual maturity and covary with mating and reproductive success (Andersson 1994). Indeed, the conspicuity of vocal sexual dimorphisms in some species prompted Darwin to speculate on the influence of sexual selection (Darwin 1871), conjecturing that deep male vocalizations tend to evolve in the context of intrasexual rivalry

as a means of exaggerating apparent size. This hypothesis has been supported by subsequent research on many species, though human voices also influence attractiveness to potential mates and may thus reflect aspects of mate quality, including underlying genes (Puts et al. 2016). Indeed, human vocal attractiveness has been the focus of an expanding literature exploring both vocal cues of mate quality and the acoustic parameters most predictive of an attractive voice.

Vocal attractiveness predicts mating success in modern human populations. Men and women with attractive voices report more sex partners, begin having sex earlier in life, and are likelier both to have and be extra-pair mates (Hughes et al. 2004). Thus, it is plausible that vocal attractiveness influenced reproductive success ancestrally. Some voices may be preferred because they convey information on nongenetic benefits, such as current fertility and provisioning ability, as well as genetic benefits conferred to offspring. For example, in both sexes, vocal attractiveness is associated with low somatic fluctuating asymmetry (Hill et al. [in press](#)), a reliable index of developmental stability across species that in humans has been associated with measures of health and quality (Van Dongen and Gangestad 2011).

Vocal Attractiveness in Men

Associations between vocal acoustic parameters and hormone levels also suggest that voices transmit information on heritable health. Simultaneously high levels of the “male” sex hormone testosterone and low levels of the stress hormone cortisol have been linked to greater immune function and attractiveness in men (Rantala et al. 2012) and have predicted lower fundamental frequency (the acoustic correlate of pitch) in men’s voices (Puts et al. 2016). This latter result is particularly relevant because fundamental frequency appears to play a major role in predicting men’s vocal attractiveness to women. Correlational (e.g., Hodges-Simeon et al. 2010) and experimental findings (e.g., Feinberg et al. 2005) initially suggested that both low fundamental frequency and low formants (the acoustic correlate of

timbre) increase men's vocal attractiveness to women. However, in recent research, fundamental frequency, but not formants, predicted men's vocal attractiveness to women when other acoustic parameters were statistically controlled (Puts et al. 2016).

In addition to potentially conveying information on health, the voice may transmit information on physical formidability. Upper-body strength and fighting prowess can be accurately assessed from the male voice (Sell et al. 2010), and masculine voices in men are related to greater body size and other measures of threat potential (Pisanski et al. 2014; Puts et al. 2012). Male voices thus provide information to potential mates not only about men's ability to provision and defend them but also about their propensity for sexual coercion. Indeed, Li et al. (2014) found that images of male-on-female aggression elicited feelings of disgust and anger that appeared to disrupt women's preference for masculinized voices. By contrast, men's voices do not appear to reflect fertility, as measured by semen quality (Simmons et al. 2011).

Women's preferences for low male fundamental frequency have been positively related to their own vocal femininity (Vukovic et al. 2010), as well as to both self-rated attractiveness (Vukovic et al. 2008) and assessments of facial attractiveness made by others (O'Connor et al. 2012). One interpretation of these results is that women who are higher in mate value can obtain and retain higher-quality mates, and women's preferences are thus calibrated according to their own mate value. However, women's self-rated health has negatively predicted the strength of their preferences for vocal masculinity in short-term, uncommitted relationships, perhaps because unhealthy women benefit most from recruiting heritable immunocompetence for their offspring (Feinberg et al. 2012). Thus, while women of higher mate value may generally exhibit stronger preferences for high-quality males, this effect related to the costs of winning high-quality mates may be counteracted by a difference in the benefits of doing so. In addition, women have been found to display a heightened attraction to masculine male

fundamental and formant frequencies during the late follicular (i.e., fertile) phase of the ovulatory cycle (Feinberg et al. 2006; Puts 2005), as well as when assessing men's voices for a short-term, purely sexual relationship (Puts 2005). This is consistent with a female strategy to procure high-quality genes at the time when those genes can be utilized and when direct benefits from men may not be forthcoming.

These associations suggest that a masculine voice may have increased ancestral men's reproductive success by helping its bearers win mating opportunities via female mate choice. Indeed, men with lower mean fundamental frequency (Puts 2005) and less variation in fundamental frequency (Hodges-Simeon et al. 2011) report more sex partners. In at least one natural fertility population, men with voices low in fundamental frequency realized greater reproductive success (Apicella et al. 2007). It is possible, however, that associations between a masculine voice and men's mating and reproductive success are more strongly mediated by success in male intrasexual competition, as Darwin hypothesized. In fact, Hill et al. (2013) found that male vocal masculinity predicted dominance, but not attractiveness, and only the former predicted self-reported number of sex partners.

Vocal Attractiveness in Women

Women's voices, too, may convey to potential mates information on nongenetic benefits. For example, female fundamental frequency decreases with age (Nishio and Niimi 2008), and women's voice attractiveness appears to peak during their most fertile years, the mid- to late twenties (Röder et al. 2013; Wheatley et al. 2014). Women's vocal attractiveness is also associated with a low waist-to-hip ratio (Hughes et al. 2004) and peaks during the late follicular phase of the ovulatory cycle (Pipitone and Gallup 2008), both of which suggest that women's voices are cues to fertility. Indeed, the ovulatory shift in female vocal attractiveness is mediated by changes in the production of the reproductive

hormones estradiol and progesterone (Puts et al. 2013; fundamental frequency did not covary with these hormones, however). In addition, women's vocal attractiveness is positively related to their facial attractiveness (Collins and Missing 2003), although it is unclear the degree to which this correlation reflects overlapping vocal and facial cues to fertility, genetic quality, or other components of mate quality.

Men prefer higher (i.e., more feminine) fundamental (Apicella and Feinberg 2009; Feinberg et al. 2008) and especially formant (Collins and Missing 2003; Puts et al. 2011) frequencies in women's voices. Women perceive female vocal femininity in both of these acoustic parameters as being attractive to men and sounding flirtatious (Puts et al. 2011), perhaps as a means of identifying the sexual competitors who pose the greatest threat. Men display stronger preferences for vocal femininity when evaluating women for a short-term, purely sexual relationship as opposed to a long-term, committed relationship (Puts et al. 2011) and when women exhibit interest in them (Jones et al. 2008), suggesting a male strategy to pursue female reproductive capacity more when expected paternal investment is low and when men's mating effort is likelier to be successful.

Considerations and Future Directions

It is important to note that because men and women's voice preferences have likely exerted important selective pressures on vocal traits in each sex, the vocal attractiveness literature has focused on heterosexual mate choice. Research on voice preferences among nonheterosexual individuals, however, can inform our understanding of a host of biobehavioral phenomena and has indicated that gay men convey vocal cues to their sexual orientation (Valentová and Havlíček 2013), exhibit more female-typical fundamental frequency (Baeck et al. 2011), and find vocal masculinity in men attractive (Valentová et al. 2013). In other ways, however, gay men are more sex typical, and scant research

has yet been undertaken on voice preferences among lesbians or those of either sex with a bisexual orientation.

An additional consideration in interpreting research on vocal attractiveness is the literature's appreciable methodological variation, which limits inferences of species typicality in vocal traits. For example, the duration of experimental stimuli (Ferdenzi et al. 2013), articulatory clarity (Kempe et al. 2013), accent (Babel et al. 2014), and breathiness (Xu et al. 2013) have all been shown to influence attributions of attractiveness, and the literature has included variation in each while not always emphasizing the influence such variation may have on findings. Future work should address this by including recordings taken from a greater breadth of populations so as to capture more variation in language, as well as speech nonconformity and its covariates (e.g., social status). Additionally, research should illuminate the connections between variation in vocalization and variation in anatomical substrates, for example, as they relate to developmental stability.

Definition

Vocal communication is the transfer of information through the auditory channel via voice production mechanisms.

Introduction

Vocal communication is ubiquitous in mammal species. As a mode of signaling, vocalizations often manifest in alarm call systems, territorial displays, and courtship rituals and are particularly well-suited for functions requiring wide broadcast. But vocal signals are used in an incredible variety of communicative contexts, many of which are extremely quiet, and between small groups of animals. Here I will describe two fundamental issues important for the study of evolution of vocal communication in humans and nonhuman animals: the distinction between adaptive signals and byproduct cues, and the concept of form and function in the structure of animal signals. I will then apply these principles to current evolutionary research on vocal behavior in humans specifically.

In mammals, the underlying brain mechanisms driving emotional vocal behavior are highly conserved and involve neural circuitry integrating the anterior cingulate to laryngeal musculature (Ackermann et al. 2014). But humans have evolved speech production that is partially distinct

both proximately (i.e., mechanistically and developmentally) and ultimately (functionally and phylogenetically). Direct connections between motor areas of the brain and laryngeal systems allow for the generation of complex speech sounds, and this production organization interfaces with many cognitive systems involved with language in a broad sense (Fitch 2000). But exactly how this dual pathway arrangement operates in real time remains to be described. Conversational turn taking, the primary context in which linguistic action occurs, is partly regulated by evolutionarily older vocal patterning, including suprasegmental prosodic variations, rhythmic coordination, and other vocal phenomena.

The study of vocal communication from an evolutionary perspective requires us to distinguish between signals and cues (Maynard-Smith and Harper 2003). Signals are behaviors or structures designed to affect the behavior of another organism, and the responses of the receiving organism are shaped by selection to be affected by the signal. That is, by design, signals typically benefit both senders and receivers. Examples of vocal signals in humans include a variety of evolutionarily conserved, nonverbal affective vocalizations, such as laughter, crying, pain shrieks, copulation calls, and emotional screaming. Language also constitutes a signaling system, transmitted primarily through speech production and working in tandem with the vocal emotional system through the integration of linguistic constituents (i.e., phonological, morphological, and syntactic) and suprasegmental prosodic features. All of the above signaling phenomena coevolved in the context of sophisticated social cognitive abilities including theory of mind, providing a platform for specialized ostensive communicative behavior (Scott-Phillips 2014). That is, because humans are able to reliably detect and signal about others' mental states and intentions, vocal signaling systems coevolved with pragmatic reasoning.

Conversely, cues are any actions or structures that were not designed to affect the behavior of other organisms but reveal information to receivers incidentally. Organisms can evolve perceptual sensitivity to cues and exploit individuals who reveal predictive information. When costly to

those revealing information inadvertently, a coevolutionary arms race can ensue where selection for reducing cues coevolves with enhanced perception of relevant cue properties. This type of scenario applies to a variety of vocal communication phenomena in humans including detecting volitional signals with deceptive intent (e.g., so-called fake laughter and crying), intentional deception in speech, fertility in female voices, and formidability in male voices, among others.

As a general principle across mammalian vocal communication, the structural forms of signals are directly tied to communicative functions. In most nonhuman vocalization systems, the sound itself is doing the majority of the communicative work, as acoustic signals are designed to have either direct effects on receivers' behaviors, or they are paired with other events to achieve eventual indirect effects (Owren and Rendall 2001). This is true for a great deal of human communication as well. For example, in the case of infant-directed speech, a caregiver might produce a loud, nonverbal utterance with an abrupt onset and perhaps even nonlinear phenomena indicating high arousal, in an effort to prevent (or interrupt) a particular behavior in a target infant. Acoustic features capture the infant's attention and cause her to reorient, thus altering her behavior. The direct impact of the prohibitive yell on the infant's physiology achieves the goal of the caregiver. The form and function relationship apparent in ID speech suggests a fair amount of universality in the sound of a variety of infant-directed utterance types, which indeed has been found across cultures (Fernald 1992).

This principle underlies the affective aspect of any kind of human vocalization. Emotional vocal signals are generated as the products of particular combinations of physiological states characteristic of different emotions, and their sound can be understood in these terms. The downregulation typical of sadness lowers arousal-linked vocal features such as loudness, pitch, and speech rate, and the high arousal of intense fear has opposing effects on screams. Besides these basic acoustic dimensions of voice such as pitch, loudness, and rhythm, spectral features also are directly tied to affective states. Again, during high arousal, the

effect of pushing air excessively through the vocal tract can be quite audible as nonlinear spectral features such as deterministic chaos and subharmonics that give vocalizations a harsh, noisy sound quality (Bryant 2013).

Many researchers examining human vocalizations from an evolutionary perspective have focused on the production and perception of sexually dimorphic vocal features. Vocal pitch in particular has been examined extensively. Pitch is the perceptual correlate of the fundamental frequency of vocal fold vibration regimes. Pubertal androgen exposure triggers growth of the vocal folds in young males resulting in lengthening and thickening that impacts vibration rates. According to the immunocompetence hypothesis, secondary sexual traits such as lowered pitch in male voices result from the effects of testosterone that simultaneously suppresses immune function. Only higher quality males, therefore, can afford to express the signal, thus making the trait attractive to females. Indeed, while immunosuppression effects of testosterone are not well established, it is fairly well documented that lower pitch in male voices has a variety of positive effects on judgments of attractiveness, dominance, body size, competence, strength, and other dimensions. Conversely, higher pitch in female voices increases men's judgments of attractiveness and is associated with judgments of greater femininity, youth, reduced body size, and higher fertility. Resonating properties of the vocal tract manifesting acoustically as formant structure also has been shown to have a variety of effects on these same dimensions, with relatively greater validity for body size in particular (for a review see Pisanski and Bryant 2018).

While sexually selected features of the voice have received considerable attention, the role of social context has been explored much less (Pisanski et al. 2016). Studies have shown that speakers often change their voices (e.g., pitch, loudness, and rhythmic properties) according to the demands of particular social contexts. For example, men have been shown to enhance masculinized features (e.g., use lower pitch) when speaking to a potential mate, and women will accentuate feminine features (e.g., raising their pitch and speaking slower) when told that their

voices will be judged by men for attractiveness. Social context also plays an important role in how a variety of nonlinguistic vocalizations manifest themselves. For instance, friends in conversation tend to laugh more spontaneously, and the resulting arousal in their laughter affords the rapid detection of their relationship across widely disparate societies, as does the generally low-arousal volitional laughter more common between strangers or newly acquainted people (Bryant et al. 2016). Arousal is not only detected in human voices—recent work has shown that judges are quite effective in detecting arousal in species quite distant from humans, including in vocal signals of birds and tree frogs (Filippi et al. 2017). This research illustrates well the power of form and function in understanding the communicative effectiveness of vocal signals, and how evolutionary processes conserve signal features that are inherently connected to signaling production and shape perceptual systems to attend to them.

Conclusion

An evolutionary adaptationist approach to communication requires theorists to distinguish between vocal signals and cues. Our understanding of specific physical features of the human voice, and how they are deployed in social interaction, is clarified by recognizing the design features shaped by selection processes on communicative behaviors. Consequently, this approach profitably connects research between humans and nonhuman animals in a way not especially common in other areas of the evolutionary behavioral sciences. The study of vocal communication is among the fastest developing areas of evolutionary psychological research. Recent advances in acoustic analysis technology, which are freely available thanks to the developers of software such as Praat, have helped facilitate new and exciting work. The current trend of conducting large-scale cross-cultural studies is also affording tremendous opportunities for understanding universals and cultural variation in vocal signaling. It is an exciting time to be

studying what is one of the most pervasive and fundamental aspects of human life.

Definition

Agonistic interactions mediated by the production of acoustic signals.

Introduction

It is late autumn in the temperate forest, the last leaves still on the trees finally surrender to the northern breeze and fall down, silently. The beams, as the sun sinks, pass through the naked branches and illuminate the forest clearing, where a large, old stag is moving restlessly around a group of quietly foraging females. Not far away, a young solitary male observes the scene. The breeding season is almost over and the young

male has not yet mated. Testosterone, flowing abundant in his blood, makes him decide to challenge the rival, in the attempt of conquering his harem. As he moves a few meters ahead, the rival spots him and, suddenly, stops, raises the head, opens the mouth, and starts uttering grave, loud roars. The young responds in the same way. A vocal competition has begun.

Vocal competitions are common in many arthropods and vertebrates, which are the only taxa that evolved the ability to communicate by means of sounds (Bradbury and Vehrencamp 2011). Acoustic signals are well adapted to mediate agonistic conflicts. Since sounds are effective on the long distance, they prevent physical contacts and reduce the risk of uncontrolled fighting escalations. Sounds are under strong morphophysiological constraints and are thus preadapted to encode reliable information about the sender's fighting ability. Sound modulation further increases the communicative potential of acoustic signals, and it allows to flexibly adjust signals to the unpredictable dynamics of the ongoing competitions.

Vocal competition can be direct or indirect. In the following paragraphs, we shall consider the effects of these two mechanisms on the evolution of agonistic signals.

Vocal Contests

The vocal contest, such as that described in the red deer, is a mechanism of direct vocal competition. Two conflicting individuals exchange agonistic signals in order to resolve conflict to their own advantage. In this communicative interaction, the actors play both the sender and the receiver role. Since the degree of conflicting interest between senders and receivers is high, agonistic signals can be evolutionarily stable only if they provide receivers with honest information about the fighting ability and the aggressive motivation of the sender (Bradbury and Vehrencamp 2011). Natural selection can guarantee the honesty of agonistic signals by imposing either strategic costs or morphophysiological constraints on their expression (Maynard Smith and Harper 2003). The roar

of the red deer is a good example of both solutions. In fact, fighting ability depends on body size and stamina (the ability to sustain prolonged energetically costly activities), and the roars of the red deer convey honest information of both these traits. When roaring, the stag retracts the mobile larynx down to the sternum (Reby and McComb 2003). The sound produced by the vibrating vocal folds resonates into the vocal tube; some frequencies are filtered out, whereas others, the formants, are amplified. The frequency of the lowest formant is strongly and negatively correlated with the length and volume of the vocal tube and, thus, with the male body size. Playback experiments have shown that the roar spectral properties affect the contest outcome, favoring the individuals with the lowest formants. Independent of body size, the fighting ability of a male depends also on how much energy stores he has and on how good he is in using the energy in controlling aerobic and anaerobic metabolic rates. In the red deer, roaring is energetically costly and involves muscles that are important during fighting. The high strategic costs of sustained vocal contests, thus, is a reliable indicator of male fighting ability.

Vocal contests are common in most acoustic-communicating species. For example, in the house cricket, *Acheta domestica*, male-male aggressive interactions typically begun with the production of stridulatory calls, which differ from mate-attraction calls in both spectral and temporal structures. In this case, honest information of male body size is encoded in the temporal properties (the number and the rate of pulses within a call), rather than in the frequency components of the call (Greenfield 2002). In territorial songbirds, vocal contests are often a mechanism for resolving boundary disputes. During the contest, birds of neighboring territories interact acoustically on a short time scale in order to assess reciprocal differences in motivation and to establish relative dominance. The dawn chorus of many territorial songbirds is an unusual example of vocal context, because it does not involve dyadic interactions between conflicting individuals. With their vigorous signaling, territorial males communicate their presence and condition to prevent rather than to prevail over potential rivals.

Indirect Vocal Competition

Unlike in vocal contests, in indirect competitions, the outcome of agonistic interactions depends on the behavior of a third-party actor, who plays the receiver role. A typical example is represented by lek breeding species, where males aggregate in large choruses and compete acoustically against each other to attract gravid females. In this case, selection promotes the evolution of acoustic traits, which might be poor indicators of fighting ability, but good indicators of sexual attractiveness. Mate choice theories of sexual selection try to understand the functional significance of mate attractiveness.

The distinction between direct and indirect vocal competition, however, is not always clear cut. In many species, in fact, the same acoustic signal may be used in both direct and indirect competition. For example, in the red deer, the acoustic properties that are important for solving intra-sexual agonistic interactions are also those perceived as most attractive by females. In contrast, in other species, direct and indirect vocal competitions conflict with each other. For example, in tree frogs and toads, males often compete for display positions within the chorus. During these agonistic interactions, males have been observed to reduce the dominant frequency of their advertisement calls, and playback experiments showed that the greater the reduction, the more effective the call was in repelling the opponent (Gerhardt and Huber 2002). Frogs and toads, however, have a poor control over the resonant frequency of their vocal folds, and the only way they have to reduce the frequency is by reducing the vibrating pressure of vocal folds, with a consequent reduction in call intensity. The intensity reduction may have no effect on the short distances at which male-male interactions occur, but it may have strong negative effects on the long distances, where male-female interactions occur. In this case, selection is expected to promote the evolution of optimal tradeoffs between the conflicting functions.

Indirect Vocal Competition in “Selfish” Choruses

Indirect vocal competition arises because signaling males tend to aggregate in spatially restricted areas. In some cases, aggregation can be explained by the inhomogeneous distribution of the limiting resources. For example, male frogs aggregate at the breeding ponds, because here is where females lay their eggs. In other cases, however, aggregation may be favored by natural selection, because the benefits it provides overcome the competition costs it imposes. This happens when group size shows either a positive allometry with the number of visiting females or a negative allometry with the number of visiting predators, or both. Whatever the reason, aggregation adds a new level of competition in the population, because males not only compete against their rivals within a chorus but, as members of a chorus, they also compete against the members of other choruses within a network. The two levels of vocal competition may interact and affect the spatial and the temporal structure of vocal activities.

Vocal competition within a chorus can cause signalers to couple their calling to that of their rivals. Coupling may occur both at the gross and at the fine temporal scale. At the gross-scale level, it usually results in synchronous calling. For example, tree frogs alternate prolonged bouts of calling with periods of silence, and they do this synchronously within a chorus. In this way, tree frogs may reduce the risk of being predated by passive listening predators, such as bats (i.e., an “acoustic dilution effect”), and, at the same time, they may increase the power of the overall signal to attract females from further away (Gerhardt and Huber 2002). In contrast, at the fine-scale level, coupling results more often in alternate than in synchronous patterns, at least in those species where the fine-scale structure of the call conveys important information for species recognition. Alternation might be interpreted as a form of “selfish” signaler cooperation, because chorusing males share the same common interest of making their own signals as detectable as possible. Males that fail to alternate would reduce their own mating success and, incidentally, that of their

neighbors. Alternation can also arise as a side effect of male-male vocal competition. In many species of frogs and insects, in fact, females show strong preferences for the male that call first (acoustic leader) (Gerhardt and Huber 2002). Males can thus compete against their closest neighbors for temporal primacy and this would result in regular antiphonal calling.

Vocal Competition in Cooperative Choruses

So far we have considered vocal competition of selfish choruses. However, in some birds and mammals with a solid social organization, vocal competition often occurs between social groups, and, at the within-group level, individuals cooperate to improve the overall calling performance (Ravignani et al. 2014). In many tropical bird species, the members of a pair are known to coordinate their songs, by accurately alternating their components. In some species, the social group includes helpers, who join to produce a complex chorus, in which individuals of the same sex sing the same phrases with near-perfect synchrony (Mann et al. 2006). Chorusing behavior in birds is thought to solve two main functions: it favors coordination among the members of a group and it improves vocal contest performances in mutual territorial defense. In primates, chorusing (mostly in the form of duetting) has been observed in a few genera only. A well-studied example is that of the singing lemur, *Indris indris* (Gamba et al. 2016). In this species, all members of a group usually sing, but the contribution changes in relation to the social rank, suggesting that chorusing not only solves the function of communicating group size and cohesiveness during the vocal contexts with neighboring groups but it may also play a role in mediating within-group social conflicts.

Conclusions

Direct and indirect mechanisms of vocal competition have favored the evolution of signals that are a reliable indicators of signalers' competitive

quality (fighting ability or attractiveness). Morphophysiological constraints preadapted some sound properties to this function. But evolutionary stability is most likely the consequence of the strategic costs of cheating: the risk of fighting escalation in vocal contests and the energetic costs of sustained calling in choruses make the bluff an economically disadvantageous tactic.

Definition

One hypothesis to explain the emergence of language in the primate lineage is that manual grooming, seen in most primates, has been gradually replaced by vocal grooming, eventually leading to the emergence of spoken language. This hypothesis is based on the observation that, similar to manual grooming, human language plays a key role in building and maintaining affiliative bonds and group cohesion. The purpose of this entry is to review the empirical literature to evaluate the vocal grooming hypothesis.

Introduction

The biological success of our species is partly grounded in a major evolutionary transition in mental capacities from self-serving, competitive to group-oriented, cooperative social relationships. Compared to other primates, humans are much more collaborative, prosocial, and amenable to social norms, with far-reaching implications at almost every level of human activity, including language. Human social interactions are highly structured joint activities during which partners are in tune with each other's intentions – the human 'interaction engine' (Levinson 2006). Linguistic discourse is a specific type of joint activity, which is characterized by rapid

exchanges of syntactic units, while its semantic content is often about others' social behavior, or gossip, and this exchange of social information appears to have a strong bonding effect on the interlocutors (Dunbar 1993).

In nonhuman primates, social bonding is mainly achieved by manual grooming, but some species have additional mechanisms that involve vocal behavior. This has led to the hypothesis that, during human evolution, manual grooming has been gradually replaced by vocal grooming as the main mechanism for social bonding, which has paved the way for the evolution of language (Dunbar 1993). Vocal grooming, in other words, has become something like the missing link in this theory of language evolution.

Manual Grooming in Primates

Social grooming ("allogrooming") plays an important role in the social fabric of primates, much beyond its primary hygienic function. For several species, there is evidence that grooming is the main way by which primates initiate and maintain social bonds, which increases tolerance between individuals and, by extension, ensures group cohesion. When choosing their grooming partners, primates and other animals are very selective and behave in seemingly strategic ways. For example, high-ranking animals receive more grooming than others, and the majority of grooming occurs between individuals of similar rank.

Grooming-driven social bonding appears to be physiologically mediated. In wild chimpanzees, for example, urinary oxytocin levels are higher after grooming with bond partners than other group members (Crockford et al. 2013), and there is also good evidence that grooming has a direct impact on an individual's fitness. In primates, grooming increases the probability that partners will help each other during fights, whereas individuals with strong social networks have higher lifetime reproductive success than less socially integrated individuals (Silk et al. 2010).

Interestingly, across species, there is a positive relation between social grooming time and group

size, suggesting that species that form large groups spend relatively more time with manual grooming than those living in small groups, due to the increased number of social relationships they have to maintain (Dunbar 1993). Time demands to maintain social relation increase exponentially for each individual with group size, and this is likely to favor the evolution of alternative and more flexible bonding mechanisms. Humans maintain around 150 stable social relationships (“Dunbar’s number”) but spend hardly any time with manual grooming. Thus, the proposal has been that, during human evolution, manual grooming has been gradually replaced by vocal grooming, which then has paved the way the evolution of language (Dunbar 1993).

Vocal Grooming

How did the transition from manual to vocal grooming take place? In many pair-living avian species, males and females produce vocal duets, which require coordination between partners and appear to play a role in social bonding. In non-human primates vocal duets are mainly between strongly bonded breeding pairs, such as in gibbons, lemurs, titi monkeys, or tarsiers. However, duets are primarily long-distance signals, suggesting they have other functions beyond pair-bonding, such as advertising bond strength to neighboring rivals, and therefore being integral components of territorial defense.

Another candidate for vocal grooming in primates is chorusing. In chimpanzees, for example, males of the same group chorus with their pant hoots, an acoustically unique long-distance vocalization. There is evidence that these joint vocal displays facilitate tolerance at feeding sites and predict support in agonistic interactions on a short-term basis, while manual grooming seems to be a better predictor of long-term social bonds (Fedurek et al. 2013).

Another relevant phenomenon is vocal convergence. In many animals, including primates, affiliated individuals adjust the acoustic structure of their calls during vocal interactions to the effect that strongly bonded individuals are more likely to produce acoustically similar calls than less

bonded individuals, but this is often at an ad hoc level (Candiotti et al. 2012). Whether these short-term acoustic accommodations function to facilitate the formation of long-term bonds or are expressions of temporary affiliations is unclear from the current data. In humans, vocal convergence is a well-documented phenomenon, described as “speech accommodation,” although similar effects are also seen in gestures, suggesting that people try to either emphasize or minimize the social difference to their interlocutors, reflecting their desire or refusal to strengthen a social bond.

Call exchanges, finally, are another potential mechanism for social bonding, which often appears in the form of coordinated vocal turn taking. Call exchanges are found in many primates, often between closely affiliated individuals, as seen in guenons, squirrel monkeys, marmosets, or macaques. In ringtailed lemurs, call exchange networks are socially more rigid than grooming networks, insofar as socially important individuals are more likely to elicit vocal responses than others (Kulahci et al. 2015). Vocal turn taking is also a key feature of human linguistic discourse, which is characterized by highly structured, rapid exchanges of short syntactic units, around 1,500 per day (Levinson 2016). In humans, the length of turns can be flexible, as can the number of speakers, but participants rigidly observe short time gaps of about 200 ms between turns. This highly conserved pattern requires participants to predict when a partner’s turn comes to an end, which is only possible if interlocutors can anticipate the forthcoming semantic content, while constructing their next utterance. This pattern is found across languages, suggesting that it is based on a biological predisposition, with possibly deep evolutionary roots.

Transitions to Language

One key prediction of Dunbar’s (1993) vocal grooming hypothesis is that vocally based social bonding has gradually replaced manually based bonding via grooming. This process is driven by evolutionary processes leading to increased group size, which will exponentially increase the

number of social relationships an individual needs to maintain and monitor. Once the number of relationships becomes too large, an individual can no longer maintain its social networks with tactile interactions alone, and selection will favor alternative mechanisms.

As mentioned before, several primates have evolved vocal duetting behavior, which is relevant for social bonding, but this is typically observed in species that live in small family units where manual grooming does not impose a significant burden on time budgets, while duets usually travel much beyond the partners' home range. Duetting, in other words, is not a good candidate behavior to model the transition, and it may have evolved as a supplementary bonding mechanism in species where exceptionally strong bonds are needed for reproduction, as in socially monogamous and cooperatively breeding species. Similar concerns have been raised for other potential precursor behaviors, such as vocal convergence, chorusing, or call exchanges.

Possibly the best candidate in the current primate literature is acoustic behavior seen during manual grooming. In our closest primate relative, the chimpanzees, manual grooming is often accompanied by a specific acoustic signal, lip-smacking, especially between closely affiliated individuals. Lip-smacking plays a key role in coordinating grooming bouts by making them longer, more reciprocated, and more intimate (Fedurek et al. 2015). Lip-smacking is also interesting because it is characterized by rhythmic facial movements that require some degree of motor control of key articulators (lips, mandibles), similar to human speech production, albeit without any larynx activity (Lameira et al. 2014). Many primates lip-smack during affiliative social interactions, but so far there is only evidence in chimpanzees for a direct link between this behavior and manual grooming.

Chimpanzee lip-smacking has thus become somewhat of the prime candidate as the missing link to human vocal interactions. While chimpanzee lip-smacking is semantically empty, it similarly seems to function in social bonding and is delivered in temporarily structured ways. One evolutionary scenario therefore is that, during human evolution, manual grooming has been

increasingly replaced by such a mechanism that, due to its contextual flexibility and articulatory control, may have been a breeding ground for the evolution of more sophisticated articulatory vocal control. There is good evidence that great apes have substantial control over their supralaryngeal vocal tract but relatively little active control over their sound-producing organ, the larynx (Lameira et al. 2014). The transition from manual to vocal grooming, in other words, may have been linked with gaining active control over sound production in line with concurrent underlying changes in the cognitive architecture.

Conclusion

The evolution of human language is one of the most debated topics in science, and the "vocal grooming" hypothesis represents one influential proposal to explain its emergence. The main argument is that, like manual grooming, language functions in maintaining affiliative bonds, the result of a gradual evolutionary change by which vocal behavior increasingly replaced manual grooming as a bonding tool. Humans form much larger groups than other primates, but rarely groom each other manually. At the same time, humans use language largely for gossiping, to strengthen their social bonds. A particular advantage of this type of vocal grooming is that it can act beyond dyadic interactions and does not interfere with other vital activities, such as foraging or traveling. Since social bonding has a strong physiological component, future research should target the impact of gossiping and other forms of vocal grooming in humans on the release of endorphins and social hormones, such as oxytocin.

The evidence reviewed here suggests that many animals use vocalizations to enhance social bonding. Prime examples are duetting, acoustic convergence, chorusing, and call exchanges, also seen in humans as joint singing, speech accommodation, and linguistic conversation. However, in nonhuman primates these vocal behaviors do not replace but often complement manual grooming, and interaction patterns are not always less rigid than during manual grooming.

Perhaps the most relevant type of vocal grooming in the animal literature is chimpanzee lip-smacking, an orofacial auditory signal that functions directly to coordinate manual grooming. It is conceivable that the common ancestor already utilized such a mechanism and that, during human evolution, lip-smacking became increasingly emancipated from manual grooming and so provided a breeding ground for the emergence of vocal control.

In sum, although vocal behavior can foster social bonds in human and nonhuman primates, it is difficult to explain the evolution of core features of human language, such as semantic content and syntactic structure, from these phylogenetically older behaviors. Acoustic signaling during grooming, such as lip-smacking, currently provides the most plausible evolutionary route for a transition to language, but it is unclear how humans gained increased vocal control, including vocal imitation and generative syntax, as well as a highly cooperative, intention-based psychology, which is essential for language. The vocal grooming hypothesis, in other words, provides a plausible scenario for the early stages of language evolution, but remains silent about the subsequent, equally essential evolutionary transitions to human language.

Definition

Nonverbal vocal characteristics that indicate one's potential to successfully acquire resources through force (physical or otherwise), threat of force, or the perceived benefits of associating with prestigious (i.e., high-ranking) social partners.

Introduction

A variety of trait dimensions such as dominance are gauged from “thin-slice” judgments of other individuals based on their physical characteristics. Inspired largely by theoretical models of same-sex competition (i.e., intrasexual selection) in non-human species, where the capacity to quickly assess another individual's dominance has obvious benefits for reproductive fitness (Puts 2010), research over many decades has explored the extent to which various acoustic properties within the voice denote dominance.

Research on vocal indicators of dominance has largely focused on the extent to which nonverbal acoustic characteristics indicate physical formidability, including body size and strength, and suggests a role for exaggerated sex-typical features in dominance interactions that are highly comparable across mammalian species (Fitch and Hauser 2003; Taylor and Reby 2010). Research over approximately the last two decades suggests, in turn, that trait judgments such as dominance are also inferred from nonverbal characteristics of the human voice. Fundamental frequency (F_0 , perceived as voice pitch) and formant frequencies (resonances of the supralaryngeal vocal tract) play a key role in displays and assessments of dominance in humans (Fig. 1) as in most other mammals (Taylor and Reby 2010). Across the animal kingdom, when an animal lowers either of these voice frequencies, this behavior typically communicates aggression or functions as a dominance display (Morton 1977). In humans, in addition to communicating aggression, low voice pitch among men indicates high levels of pubertal and circulating testosterone, whereas low formants predict a relatively larger body size. Both

voice features are also sexually dimorphic – lower among males than females – as is typical for many other primate species (Puts et al. 2016). Thus, dominance judgments may contain some degree of accuracy; however, individuals may also modulate (or “fake”) vocal characteristics to their strategic advantage during competition. Each of these topics is discussed in turn below.

Voice as an Index of Body Size and Strength

Physical body size, including height, weight, and muscle mass, is an indicator of social dominance, especially for men. Across diverse human cultures, taller men have greater social rank, earn more, report more sexual partners, and have more children than do shorter men (Pisanski and Feinberg 2013). The relationship between body size and social rank in men suggests that size may be advertised, and even exaggerated (see later section on Reliability and Deception), through multiple modalities including the voice and that the ability to accurately estimate another individual's body size is likely to be advantageous in many social and competitive contexts.

The earliest studies with humans in this domain focused on F_0 , a key acoustic parameter in vertebrate vocal production related to the rate of vocal fold vibration and perceived as voice pitch (Suthers et al. 2016). Bioacoustic analyses have recently broadened to include vocal tract resonances, termed formant frequencies or formants. This fruitful shift in focus emerged after the application of source-filter theory, originally conceived as a model of human speech production, to the study of nonverbal communication in mammals (Taylor and Reby 2010). Based on the source-filter framework, human vocal signals are produced by vibration of the vocal folds situated within the larynx (the source) and are subsequently filtered by the supralaryngeal vocal tract comprised of the oral and nasal cavities and pharynx situated above the larynx (the filter; illustrated in Fig. 1a).

Larger vocal folds will generally produce a lower F_0 , but this relationship is neither strictly

Vocal Indicators of Dominance, Fig. 1 (a) Sagittal MRI of the human vocal apparatus depicting the larynx/vocal folds that affect voice F_0 and the supralaryngeal vocal tract (*in bold*) that affect formants. Formants most reliably predict human body size. (b) The *upper left* spectrogram represents a low-pitched voice typical of a man, with lower F_0 and more closely spaced harmonics (integer

multiples of F_0). The *right* spectrogram represents a higher pitched voice typical of a woman. (c) The *lower left* spectrogram represents a voice with relatively lower and more closely spaced formants, typical of a taller individual with a vocal tract length (VTL) of 20 cm. The *right* spectrogram represents a shorter individual with a VTL of 14 cm (Adapted with permission from Pisanski et al. 2016a)

linear nor allometric (Titze 2011). Indeed, while F_0 predicts differences in body size across different species of mammals (Charlton and Reby 2016) and primates (Ey et al. 2007), and even between the sexes in humans (Fig. 1b), F_0 explains less than 2 % of the variance in height or weight *within* same-sex samples of adult men or women (Pisanski et al. 2014, 2016b). In contrast, the length of the supralaryngeal vocal tract (vocal tract length, VTL) scales fairly allometrically with height and body mass in humans and in many other mammals, even after controlling for sex and age. Relatively larger men and

women thus tend to have longer vocal tracts and, as a consequence, lower more closely spaced formants and a more resonant voice (Fig. 1c). A recent meta-analysis confirmed that formants explain several times more variance in men's heights than does F_0 (Pisanski et al. 2014).

Formants are the most reliable vocal correlate of human height and weight. However, numerous voice parameters including F_0 , formants, and perturbation parameters such as jitter, shimmer, and harmonics-to-noise ratio correlate with the *shape* of men and women's bodies. Some of these voice parameters can, for instance, indicate the ratio of

men's shoulder or chest circumference to their hip circumference (Hughes et al. 2009; Pisanski et al. 2016b), which is of note as body shape can also function to communicate dominance.

Collectively, work to date suggests that acoustic parameters indicate various proxies to dominance (e.g., physical formidability). As certain acoustic parameters are exaggerated to a much greater extent among males than females (i.e., are highly sexually dimorphic, e.g., *voice pitch*; Puts et al. 2016), work on vocal indicators of dominance in humans complements that in other species, where sexually dimorphic physical characteristics are related to various measures of dominance rank more generally (see Watkins et al. 2010 for discussion). Recent work further suggests that testosterone-dependent vocal characteristics in male primates, including humans, may play a key role in male-male competition (see Fedurek et al. 2016 and Puts et al. 2016 for recent discussion). Below, we provide an overview of the relationship between sexual dimorphism and social perceptions of dominance from voice, focusing primarily on research that uses technology to experimentally alter voice pitch and empirically test its subsequent effect on assessments of dominance.

Voice-Based Assessments of Dominance

A good deal of research on sexual dimorphism and voice perception in humans has focused on perceptions of individuals whose voices vary in *F0*/pitch. Masculine vocal characteristics (i.e., low *F0*/pitch) are typically manipulated via an algorithm in established software (Praat; Boersma and Weenink 2016) that alters pitch, while other aspects of the voice remain unaffected, with manipulations roughly equivalent to 20 Hz sufficient to alter perceptions of voices including perceptions of the speaker's masculinity. Using these methods, and when judging both men and women, masculinized versions of voices are perceived as relatively more dominant than are feminized versions of the same speaker's voice (e.g., Feinberg et al. 2006; Jones et al. 2010; Puts et al. 2007, 2016).

Voice pitch alterations have a greater corresponding effect on the perceived dominance than attractiveness of men, suggesting an important role for vocal characteristics in male-male competition (see Puts 2010). Moreover, lowering voice pitch increases perceptions of leadership potential in both men and women (Klofstad et al. 2012), the number of votes earned by hypothetical election candidates (Tigue et al. 2012), and is negatively associated with judgments of cooperativeness. In contrast, low formants appear to increase judgments of cooperativeness, perhaps because they indicate dominance in the context of prestige versus threat (see Knowles and Little 2016). These associations between dominance and vocal characteristics may generalize to actual social outcomes, as low-pitched CEO's manage larger companies (in financial terms) and have longer tenures at their firm than do CEOs with higher pitched voices (Mayew et al. 2013).

There appears to be some cross-cultural consensus in associations between voice and formidability. Comparing between two distinct cultures, Puts et al. (2012) found that low *F0* predicted arm strength among Tanzanian Hadza men, whereas low formants predicted arm strength among American men. However, both *F0* and formants predict measured strength (i.e., physical maturity) of peripubertal males of the Tsimane (Hodges-Simeon et al. 2014). Among the Hadza, both men and women judge opposite-sex individuals with low-pitched voices as better at acquiring resources (hunting/gathering) compared to individuals with high-pitched voices (Apicella and Feinberg 2009). Collectively, vocal characteristics such as pitch are associated with indices of dominance across a variety of studies and may function as a reliable indicator of actual dominance.

Reliability and Deception in Vocal Indicators of Dominance

Provided a signal remains reliable on average (i.e., in this instance vocal parameters such as pitch/formants), species may exploit this signal to their strategic advantage when competing for mates

and/or resources (reviewed in Mokkonen and Lindstedt 2015). Although vocal parameters are largely constrained by body size, wherein larger species with larger larynges and longer vocal tracts will typically produce lower frequency calls than smaller species (Fitch and Hauser 2003), the vocal anatomy of many mammals has undergone morphological modifications that may function to exaggerate apparent size and, in turn, dominance (Charlton and Reby 2016). Some researchers, for example, propose that the human larynx descended in order to communicate dominance via size exaggeration to conspecifics (Fitch and Hauser 2003). This also appears true for males of several deer species, whose mobile larynges are positioned unusually low in the vocal tract and descend even further during competitive interactions with other males, resulting in a lowering of formants (Taylor and Reby 2010). Also consistent with this proposal, many mammals are known to vocalize in a lower register to convey dominance, threat potential and aggression, and conversely in a higher register to indicate submissiveness or cooperation (Morton 1977). Nevertheless, the extent to which this behavior is volitional when observed in mammals, including nonhuman primates, remains unclear (Pisanski et al. 2016a).

Recent work suggests that humans can behaviorally modulate the fundamental and formant frequencies of our voices volitionally and on demand, such as when asked to imitate a masculine or feminine and physically large or small person (Pisanski et al. 2016a). Humans also modulate these voice parameters when speaking to a potential mate or sexual rival and probably in a range of other social contexts such as job interviews or political debates. Indeed, recent work suggests that deliberate alterations of voice pitch may reduce the potential costs of conflict with observers (i.e., by sounding more dominant; Fraccaro et al. 2012). Further work on social modulation of vocal characteristics in the context of contest competition is needed. In addition, in light of recent work on dominant men's preferences for cues to dominance in other men who produce humor and the potential role of dominance in ally choice among males (Cowan

et al. 2016), further work on the extent to which people integrate social knowledge of same-sex peers (e.g., their cooperativeness as indicated through humor) with knowledge of their dominance from voice will likely prove fruitful.

Conclusion

Inspired in part by sexual selection theories that associate exaggerated sex-typical features in males with measures of success in contest competition, a great deal of research has explored relationships between vocal characteristics and the physical characteristics of the speaker. This research suggests that masculine vocal characteristics (i.e., relatively low fundamental and formant frequencies) are reliable measures of dominance, particularly in men, and that judgments on this trait dimension based on vocal cues may influence important social outcomes such as our choice of leaders. More recent work in nonhumans also suggests potential relationships between testosterone and voice production in the context of male-male competition, and work on human voice perception and production is beginning to uncover a role of voice pitch modulation used to “deceive” potential rivals.

Voice Pitch

Janie Johnson and David A. Puts
Department of Anthropology, The Pennsylvania
State University, University Park, PA, USA

Synonyms

[Vocal fundamental frequency](#); [Voice depth](#)

Definition

The perceived degree of height or depth of the voice.

Introduction

Pitch is the most salient property of the voice and describes its “highness” or “lowness” (Titze 2000). The perception of pitch is influenced by multiple acoustic parameters such as amplitude and resonant (or formant) frequencies; however, the primary determinant of pitch is fundamental frequency (F_0), the rate of vocal fold vibration during phonation (Titze 2000). Indeed, pitch and F_0 are often used as though they are nearly synonymous, though the former is a perceptual feature whereas the latter describes the physical properties of the sound waveform.

Voice Pitch Variation and Modulation

Between-individual variation in habitual speaking F_0 is contingent upon differences in vocal fold length and thickness, but individuals also modulate their pitch, both consciously and unconsciously, across contexts. In many animal species, voice pitch is lowered to signal

aggressive potential and raised to signal deference, and this pattern is also apparent across languages in the use of lowered pitch for commands and raised pitch to indicate questions (Ohala 1984). A person might deliberately modulate pitch to convey a specific impression, such as lowering pitch when assuming a leadership role, or pitch might involuntarily rise with increasing tension on the vocal folds during stressful situations (Puts et al. 2006).

Habitual voice pitch is also one of the most sexually differentiated secondary sex traits in humans. During sexual maturation, the influx of androgens in males triggers a disproportionate growth of the vocal folds, leading men to have longer (by approximately 60%) and thicker vocal folds than women (Titze 2000). These anatomic changes produce an adult sex difference in F_0 of around five to six standard deviations (Puts et al. 2012).

Sexual Selection and Voice Pitch

The decrease in male voice pitch at puberty and its associations with mating success (Puts et al. 2006) and reproductive success (Apicella et al. 2007) suggest a role of sexual selection favoring lower pitch in men. Across anthropoid primates, males tend to evolve lower frequency vocalizations relative to females during evolutionary transitions to polygyny, where male mating competition is intense, and reduced F_0 sexual dimorphism tends to evolve during transitions to monogamy (Puts et al. 2016).

In humans, heterosexual women also tend to prefer men's voices that are lower than average in pitch (Feinberg et al. 2005), especially when the women are in the fertile phase of the ovulatory cycle (Puts 2006) and are rating the voices for a short-term sexual relationship as opposed to a long-term, committed one (Puts et al. 2016). Women may exhibit this pattern of preferences in part because a low male voice pitch signals the possession of genes that increase immune system function (Feinberg et al. 2005). In two studies, low male F_0 was associated with high testosterone and low cortisol levels, a hormonal

regime that has previously been linked to immunocompetence (Puts et al. 2016).

While low F_0 may have evolved in men partly because of its function in mate attraction, low F_0 more effectively increases other men's perceptions of a man's social and especially physical dominance (Puts et al. 2007, 2016). In one study, men also modulated their voice pitch according to their perceptions of relative dominance, raising their F_0 when speaking to a competitor whom they perceived as dominant to them and lowering F_0 when they perceived themselves to be more dominant (Puts et al. 2006). Thus, it appears likely that a low F_0 may have been favored primarily for its role in male intrasexual competition and to have played a relatively smaller role in mate attraction. Associations between a low male F_0 and taller stature, higher testosterone, and lower cortisol, as well as evidence that men lower their F_0 when they perceive themselves to be dominant, suggest that low F_0 is a valid, if modest, indicator of men's threat potential to other men.

At the same time, higher-pitched female voices may have been shaped by male mate choice. Although female F_0 does not exhibit a change at puberty as in men, men rate women's voices that have been experimentally raised in F_0 as being more attractive than the same voices with F_0 lowered (Jones et al. 2010). However, this effect may be due to demand characteristics or to the conflation of F_0 with timbre (measured by formant frequencies); when other acoustic parameters were statistically controlled in a multiple regression model, women's formant frequencies predicted their vocal attractiveness to men, but F_0 did not (Puts et al. 2016).

Conclusion

In sum, voice pitch is used in communication across animals to signal dominance and deference, perhaps because a low pitch increases apparent size (Ohala 1984; Puts et al. 2016). Given this social function and possible associations with immune function, it is perhaps not surprising that voice pitch would play a role in mate attraction and same-sex rivalry.

Volunteering Publicly

Gareth Craze
Case Western Reserve University,
Cleveland, OH, USA

Synonyms

[Conspicuous prosociality](#); [Public display of altruism](#); [Public othermindedness](#)

Definition

The conspicuous performance of voluntary acts to serve others despite the potential costs borne by oneself.

Donating one's time and efforts to assist others or advance a cause, without any expectation of recompense, is at the heart of volunteerism. Research in much of social psychology has unearthed a range of the proximal factors that predict voluntary behaviors on the part of individuals, including mood, number, and type of observers or bystanders, personality traits, degree of empathy, and latent mood (Penner and Finkelstein 1998). While these factors go a long way to explaining the situational contingencies of how volunteerism arises in particular contexts, it is useful to consider whether there is a meta-theoretical account of why behavioral patterns consistent with volunteerism would arise in the first place.

Costly signaling theory (CST) provides such an account. It is predicated on the notion, now widely supported in a vast swathe of literature (particularly from fields such as behavioral ecology, ethology and biological anthropology; see e.g., Bird et al. 2001; Gintis et al. 2001) and originally drawn from the theoretical framing of

the handicap principle (Zahavi 1975), that individuals will incur costs to themselves (in terms of energy expenditure, undertaken risk, or proffering of economic or social resources, for example) as a means of publicly broadcasting information about their positive individual qualities. A tried-and-true exemplar from the literature has been the peacock's tail, for which the size and visual resplendence of this plumage is commensurate with its high metabolic and maintenance costs. Ergo, any peacock with the ability to entail such personal cost for the sake of a public display of ornamentation must be of sufficient genetic quality – and thus individual fitness as a mate or ally – to warrant being looked upon favorably by its conspecifics.

Behaviors such as public acts of volunteerism serve a similar function in humans. They serve as a conspicuous presentation of one's capacity to incur costs without enjoying any immediate reciprocation. In performing such acts, and outwardly displaying their ability to absorb the personal impact of doing so, the volunteer is publicly signaling their own status or level of prestige (Hauert et al. 2002). In the process, the volunteer is not merely advertising a one-shot instance of volunteerism (even though this might actually be the case) but is also more broadly showcasing their personal disposition toward engaging in such prosocial acts *generally*, as well as conveying the kinds of prosocial personality characteristics – sympathy, helpfulness, and othermindedness, for example – that would attest to such a general inclination toward prosociality (Griskevicius et al. 2007).

Of course, this kind of deep-rooted evolutionary logic does not suggest that volunteers are only engaging in volunteerism for the self-serving benefits that might be realized by participating in such prosocial behavior. There undoubtedly exist an array of proximal motivations why some people might publicly volunteer for purely selfish reasons in some situations, but this is not what CST is premised upon. Rather, CST holds that the psychological inclination to perform acts of public volunteerism *at all* has an adaptive calculus behind it; one which unconsciously steers individuals toward performing acts of public

volunteerism because it will ultimately increase one's perceived value within a group and in turn improve their evolutionary fitness and capacity to propagate their genes.

Vygotskian Intelligence Hypothesis, The (Moll Et Al., 2007)

Alfredo Ardila

Sechenov University, Moscow, Russia

Albizu University, Miami, FL, USA

Florida International University, Miami, FL, USA

Synonyms

Culture and intelligence; The zone of proximal development

Definition

Humphrey (1976) proposed that the major engine of primate cognitive evolution was social competition. Vygotsky (1930–1980) also emphasized the social dimension of intelligence, but he focused on cultural aspects such as collaboration, communication, and teaching. Moll and Tomasello (2007) attempted to integrate both points of view and proposed that primate cognition in general was driven mainly by social competition, but beyond that the unique aspects of human cognition were driven by, or even constituted by, social cooperation.

Introduction

The evolution of human behavior has represented a major research area during the last decades (e.g., Hart 2018). Different interpretations have been proposed. Sometimes competition has been emphasized where other times, group collaborations had been considered critical in human survival (Campbell 2017). These two interpretations have been extensively discussed for a very long time. Although both points of view are not necessarily contradictory, they can potentially be complementary.

Origins of Cognition

The idea that competition plays a major role in human evolution has been proposed by different authors. Humphrey (1976) presents a clear example of this point of view. In this proposal, the fundamental idea was a kind of race in which those individuals, who outsmarted the others, were in advantage and had better possibilities to survive.

A quite different point of view was proposed, but other authors, such as Vygotsky (1930–1980), also assumed the social and cultural origin of intelligence, but emphasized that collaboration, communication, and learning were crucial in the evolution of human cognitive abilities and social progress. Vygotsky stated that social interactions with parents and other figures are crucial in the development of cognitive abilities. In this regard, communication was initially a social communication, later a private communication, and finally an inner speech. This inner speech represents a basic instrument of thought and cognition (Vygotsky 1934–2012).

Noteworthy, humans are by far the most cooperative primate species. Humans live in social groups and develop specific ways of life (“culture”) shared by all the members of the social community (Richerson and Boyd 2005).

Tomasello et al. (2005) proposed an integrative point of view: they argued that primate cognition, in general, was driven initially by social competition. But because of the need to create complex technologies and systems of symbols, social cooperation was not only important but also essential. Moll and Tomasello (2007) argue that regular cooperative activities during childhood result in developing significant forms of cognitive representation and development of complex intellectual abilities.

Conclusion

The dichotomy competition/cooperation can be understood as processes of individual selection versus processes of group-level selection. Multilevel selection theories emphasize that empathy, altruism,

and reciprocity can be the bases of human social cooperation (Fehr and Gächter 2002). It seems reasonable that a variety of evolutionary processes were involved in human evolution, and, ultimately, the causes of these evolutionary changes could have been affected by different evolutionary moment and different living conditions.

So, the points of view presented by Humphrey (1976) and Vygotsky (1930–1980) are not necessarily exclusive, but could both have been involved in human cultural development at different historical moments.

Waist-to-Hip Ratio

Barnaby J. W. Dixon
School of Psychology, The University of
Queensland, Brisbane, QLD, Australia

Synonyms

[Body shape](#); [Gluteal–femoral region](#); [Hour glass](#)

Definition

The waist-to-hip ratio (WHR) is an anthropometric measure of body shape. It is calculated by taking the distance around the waist at its narrowest point and by dividing the distance around the hips and buttocks at their widest points. In evolutionary theory of human mate preferences, WHR was suggested to have evolved via sexual selection as a cue of gender, health, and fertility in women.

Introduction

Almost 25 years ago, Devendra Singh (1993) proposed that the distribution of body fat in women evolved via sexual selection as an honest cue of youth, health, and fertility. This chapter revisits Singh's iconic hypothesis in light of contemporary empirical findings and asks how sexual selection has shaped the evolution of body fat distribution in women and men.

Sexual Dimorphism in Human Body Composition

In comparison to nonhuman primates, differences between men and women in overall body size are not striking. While there is considerable overlap in body composition between the sexes within populations and pronounced cross-cultural differences in body composition, muscularity and body fat are sexually dimorphic (Wells 2007). Men tend toward a more android physique, characterized by greater stores of upper body musculature (Wells 2007). Women tend toward a more gynoid physique, wherein fat is deposited around the hips, buttocks, and thighs, collectively referred to as the gluteal–femoral region (Wells 2007). A simple way to measure gluteal–femoral fat distribution is via the waist-to-hip ratio (WHR), which is calculated by taking the distance around the

waist and dividing it by the distance around the hips and buttocks.

Among premenopausal young adults from Western populations, women's WHRs range from 0.67 to 0.80, while men's range from 0.85 to 0.95 (Cashdan 2008). These sex differences in body composition first emerge during adolescence under the actions of sex steroids (Wells 2007), principally androgens, which drive the deposition of muscle in the upper body, and estrogens, which inhibit muscle accumulation while promoting a gynoid fat distribution (Wells 2007).

As young women approach sexual maturity, a lower WHR predicts the onset of menarche (Lassek and Gaulin 2008) and is associated with maintaining regular menstrual and ovulatory cycles in young adulthood (Singh and Singh 2011). In adulthood, levels of the hormone estradiol relative to progesterone, which predicts natural rates of fertility, has been reported to be highest among women with the lowest WHRs and largest breasts (Jasienska et al. 2004). Low WHRs are also associated with higher rates of successful in vitro fertilizations and artificial inseminations (Singh and Singh 2011). During pregnancy, gluteal–femoral fat reserves are mobilized to provide energy during gestation, particularly during the third trimester for fetal neural development and postpartum for lactation (Lassek and Gaulin 2008). A low WHR also allows for a stable center of balance for bipedal locomotion during pregnancy, and increases in maternal central adiposity are associated with healthier infant birth weight (Singh and Singh 2011). WHR also changes across the lifespan, so that as women approach menopause, WHRs enter the masculine range and are less hourglass in appearance (Singh and Singh 2011).

Sexual Selection on Female WHR and Singh's "First Pass Filter" Hypothesis

Sex differences in morphology can emerge via a form of natural selection called sexual selection, where competition among individuals to fertilize the gametes of the opposite sex drives the

evolution of behavioral displays, ornaments, and armaments. Sexual selection can act on traits employed during same-sex competition, such as weaponry or visually conspicuous markers of social rank, or ornamentation that enhances sexual appeal. Men's preferences may have been shaped during the early phases of human evolution to recognize those aspects of physique that would enhance their reproductive success (Singh and Singh 2011). Singh (1993) was the first to propose that a low WHR and an hourglass physique in women were sexually selected by male mate choice. He hypothesized that a low WHR represented a "first pass filter," guiding men's initial assessment of women's mate value in ancestral environments as an unambiguous cue of gender, health, youthfulness, and fertility (Singh 1993).

Cross-cultural variation in the attractiveness of low WHRs in women

The fact that WHR conveys such significant information about the mate value of a woman suggests that men in all societies should favor women with a low WHR over women with a high WHR for mate selection or at least find such women sexually attractive. Singh (1993, p. 305)

Singh (1993) reported in a sample of young men from the USA that preferences were greatest for a low WHR of 0.7 and proposed that men's preferences should be similar cross-culturally, as men tend to value youth and healthiness in long-term mate across cultures. Replications of Singh's (1993) study that were restricted to industrialized cultures such as England, Germany, Poland, China, the USA, and New Zealand reported that men tend to prefer low WHRs of 0.6–0.7 (reviewed in Brooks et al. 2015). However, among the Bakossi of Cameroon, who live primarily as subsistence horticulturalists, men judged a more masculine WHR of 0.8 as most attractive for both long- and short-term relationships (reviewed in Brooks et al. 2015). Similarly, Shuar men of the Ecuadorian Upper Amazon preferred WHRs of 0.7 and 0.8 when controlling for

body weight (reviewed in Cashdan 2008). The Matsigenka of Peru, a culturally isolated population of slash and burn agriculturalists, preferred a WHR of 0.9 (reviewed in Cashdan 2008). Finally, among the Hadza hunter-gatherers of Tanzania, men's preferences were initially reported to be highest for a WHR of 0.9 (reviewed in Cashdan 2008). However, a follow-up study employing stimuli in profile view that looked more like Hadza women revealed that men preferred a WHR of 0.6 (reviewed in Cashdan 2008).

Many of the findings from these studies suffer from important methodological drawbacks. The stimuli were manipulated to only vary in WHR by tightening or widening the midriff, which confounds WHR with body mass index ($\text{BMI} = \text{weight} / \text{height}^2$; Tovée et al. 2006). In an attempt to address these issues, studies instead employed photographs of female patients taken before and after elective cosmetic surgery to alter their body shape (Singh et al. 2010) and found that low WHRs elicited neural reward responses in fMRI studies (Singh and Singh 2011) and were judged as most attractive across several Western and small-scale societies (Singh et al. 2010). However, these stimuli presented only the gluteal–femoral region, which does not allow height relative to weight to be visually assessed.

This debate became more complex when cross-cultural research using full body stimuli reported that BMI accounted for significantly more variance than WHR in women's attractiveness (Tovée et al. 2006). Similarly, other research using full body stimuli reported that the abdominal depth and the volume–height index are significant contributors to female physical attractiveness (reviewed in Brooks et al. 2015). Further, visual attention when assessing female attractiveness shares stronger associations with judging body fat than WHR with minimal differences reported as a function of WHR (reviewed in Brooks et al. 2015). Finally, computer models of women's fat distribution around the hips, buttocks, and thighs demonstrated that WHR as a contributor to body shape is best understood in light of increases in BMI (reviewed in Brooks et al. 2015).

Prevailing environmental, ecological, and social factors may give rise to these cross-cultural differences in WHR and body weight. Female physiques are more robust in horticulturalist settings, possibly because women engage in manual labor which drives higher androgen levels and more masculine WHRs (Cashdan 2008). Variation in preferences for body shape and size may also be influenced by a “visual diet,” wherein the distribution of body types that people are accustomed to seeing within their given cultures underpins preferences (Boothroyd et al. 2012). For example, indigenous Zulu men preferred a much higher female BMI than Zulu migrants to the UK, who tended to prefer a BMI equivalent to that of UK born men (Tovée et al. 2006). Thus, the ecological context and the local distribution of body types to which individuals are accustomed to seeing may influence the direction of preferences for female body shape.

Multivariate Selection on Preferences for Female Body Shape

Perhaps the debate surrounding the role of WHR in women's mate value became so complex due to a narrow focus on the effects of singular or a small number of indices of shape or size. Examining single traits cannot determine the strength of selection on components of WHR or how WHR contributes in concert with other bodily indices to shape physical attractiveness (Brooks et al. 2015). Manipulating one trait, such as waist girth, might change how attractive a body is judged via interactions with other bodily traits like abdominal depth or BMI. Thus, unpacking how bodily indices exert independent or interacting effects on overall physical attractiveness is complicated by their intercorrelated nature. To address this complexity, evolutionary biologists have developed selection analysis, wherein the principle dimensions of nonlinear and linear selection are characterized using linear and nonlinear multiple regressions to uncover the true targets of selection (Brooks et al. 2015).

A recent study combined multivariate selection analyses with experimental manipulations of

suites of bodily traits using computer-generated avatars (Brooks et al. 2015). In this study, avatars served as “progenitors” from which “clonal daughters” were created using computer algorithms by making minor changes to 24 bodily indices. In an online experiment, bodies were allowed to “evolve” via attractiveness ratings over eight generations (Brooks et al. 2015). From the first generation to the eighth generation, selection was strongest on the waist with preferences being higher for smaller waist girths, followed by preferences for slender buttocks and longer legs so that bodies became progressively taller and slimmer. WHR was also an important factor in women’s attractiveness and converged on a WHR of approximately 0.7. However, the buttocks continued to become slimmer, while waist girth evolved more rapidly than the buttocks, suggesting that preferences for low WHRs of 0.7 were dragged along due to strong selection acting on slender waists rather than direct selection on lower WHRs. These findings highlight the multivariate complexity of how sexual selection may shape the evolution of bodies and suggests that the role of simple measures of shape and weight may be of less importance than selection for waist girth and overall slenderness.

Conclusion

Almost 25 years from Singh’s (1993) seminal article, a great many advances have been made on our understanding of how body fat distribution influences attractiveness. His suggestions for culturally universal preferences were not supported, and subsequent cross-cultural research has highlighted a key role for BMI in accounting for variance in women’s attractiveness. Building on this work, multivariate selection analyses and evolutionary selection experiments have paved the way for determining the targets of sexual selection among suites of correlated bodily indices. Finally, studies integrating prevailing cultural, social, and ecological factors have made advances toward our understandings of what

maintains variation in preferences within and between cultures. The task moving forward may be to employ multivariate selection cross-culturally and determine the strength of selection on body shape in variable ecological and economic contexts.

Definition

“War” is an armed conflict between nations or organized groups such as tribes, gangs, kin groups, or political factions.

Introduction

It is obvious that warfare is a highly cooperative activity that requires good communication and cooperation with allies and intelligent self-control (Tooby and Cosmides 2010), but there has been a long-standing disagreement among historians and social scientists regarding the origins of human warfare. In the last couple of decades, evolutionary scientists have brought yet another perspective to bear on this issue.

The first point to be emphasized is the extent to which war is almost exclusively a male activity. In spite of the diversity to be found across human societies, there has been no historically documented case of organized fighting and killing by groups of women against other groups of women. The consistency with which males are the organizers and perpetrators of group conflict has led many scholars to conclude that the male propensity for group violence is rooted in more

than the learning of culturally prescribed gender roles. Most evolutionary psychologists believe that the roots of warfare can be traced to the competition between males for status and access to women (McAndrew 2017).

Male Competition for Mates Is Intense

The adaptive problems faced by men and women throughout history were quite different, and aggression proved to be a more adaptive response for males than for females. Sexual competition for mates has always been more intense among males than among females, especially in the polygamous societies that appear to have been typical in the prehistoric human world.

The stakes were very high for men in this environment, as the winners of this competition would come away with the greatest number of women (and the most desirable women). The losers ran the risk of genetic annihilation by their failure to successfully win the status and resources necessary to attract mates. Historically, powerful men have always enjoyed greater sexual access to women than men lower in the pecking order, and violence, including war, can often be traced to this grim struggle for status and mates among men.

Violence committed against the right people at the right time has commonly been a ticket to social success. For example, among the Yanomamo of South America, men who had killed other men, especially during wars and skirmishes with other villages, acquired significantly more wives than men who had not yet killed anyone (Chagnon 2013). Because having killed someone in war was usually good for one's reputation, many societies developed ceremonies for recognizing such accomplishments. In modern societies, these take the form of prestigious awards such as the Congressional Medal of Honor in the United States, and many countries have national holidays to celebrate the heroism of those who have fought and/or died in wars.

To insure that public recognitions of valor during war serve as honest signals of heroic behavior, sanctions may be brought to bear against individuals who falsely claim to have attained military

honors. For example, in the United States, the “Stolen Valor Act of 2005” was signed into law by President George W. Bush to prohibit the unauthorized wear, sale, or manufacture of military decorations and medals. This law was extended by the “Stolen Valor Act of 2013” signed into law by President Barack Obama. The 2013 law makes it a crime for a person to fraudulently claim to have received military medals and decorations.

Could War Heroism Be Adaptive?

Evolutionary psychologists believe that even apparently selfless impulses such as volunteering to fight in a war must provide some adaptive advantage for individuals. Costly signaling theory (Bereczkei et al. 2010; Bliege Bird et al. 2005; Grafen 1990; McAndrew 2002; Zahavi 1977) suggests that conspicuous war heroism may be a way for individuals to advertise desirable personal qualities that increase the likelihood that they will be chosen as a mate or an ally and be positioned for access to future resources.

Many studies demonstrate that people who sacrifice for the group by engaging in costly altruistic activities do in fact achieve elevated social status, respect, and recognition as a result of their public selflessness (McAndrew and Perilloux 2012a, b; Willer 2009). For a costly signal to be effective, it must honestly convey valuable information about the individual sending the signal, and it must be impossible to fake. No researchers suggest that heroes consciously sit down and calculate all of the benefits that will come their way if they survive the heroic action. Rather, it is thought that such impulses have been selected for because heroic behavior has provided competitive advantages for men throughout human history.

Have Men Evolved to Make War?

Dutch psychologist Mark van Vugt proposed the *male warrior hypothesis* as a way of explaining the results of research demonstrating that men show stronger group identification and more

cooperation with ingroup members than do women during times of threat from outside groups (Van Vugt et al. 2007). His theory suggests that men have evolved a predisposition to engage in collective cooperative aggression against outgroups, a tendency that has likely been strongly reinforced through culture traditions and socialization. Puts (2010) has also pointed out that men tend to form more hierarchical same-sex coalitional groups than do women and that they are more likely than women to make strong ingroup/outgroup distinctions that result in the dehumanization of outgroup members (Buss 2015).

A team of European psychologists explored the proposition that war provides an arena for men to compete and impress both their male rivals and females who might be potential mates (Rusch et al. 2015). In one study, they found that 464 American men who had won the Medal of Honor during World War II eventually had more children than other US service men who had not been so heroically distinguished. This is consistent with the idea that heroism gets rewarded with greater reproductive success.

In a second study, 92 women rated the sexual attractiveness of men who had behaved heroically in war as being higher than that of soldiers who had served but not been identified as heroes. Tellingly, women did not show this increased attraction toward men who had behaved heroically in sports or business situations. A third study revealed that behaving heroically in war does not increase the attractiveness of female war heroes to men. In summary, heroism in time of war is sexier than any other kind of heroism but only for men. Similarly enhanced access to females has been documented for males who join violent street gangs (Palmer and Tilley 1995).

Young men are particularly concerned with status and heroic opportunities for sound evolutionary reasons. In early human societies, competitive success or failure in early adulthood determined a man’s standing in a social group for the rest of his life. It wasn’t possible to simply hit the “reset” button and join another group, so what happened during the teen years mattered a lot. For this reason, high-risk competition

between young males provided an opportunity for “showing off” the abilities needed to acquire resources, exhibit strength, and meet any challenges to one’s status (Iredale et al. 2008; McAndrew 2009). Consequently, heroic or even recklessly daredevil behavior was rewarded with status and respect – assuming, of course, that the young man survived the ordeal. Displaying heroism in time of war was a primary way of accomplishing these goals. Hence, it should not be surprising that historical data confirm that the proportion of a population made up of young men is one of the best predictors of when a society is most likely to go to war (Mesquida and Wiener 1996).

The relentlessness of risky, aggressive behavior by young males has prompted Wilson and Daly (1985) to label this behavioral tendency the “Young Male Syndrome.”

The results of the annual “Darwin Awards” competition offer a tongue-in-cheek confirmation of the tendency of young males to behave recklessly. The Darwin Awards feature those individuals who have lost their lives in dramatic fashion during the previous year by taking pointless risks. For the 5-year period from 2010 to 2014, the Darwin Award winners were skewed toward men by a margin of 38–5, with two of the five women who made the list getting there by being talked into having sex with men under less than rational circumstances (DarwinAwards.com).

Men are sensitive to signals that advertise the physical strength, fighting ability, and aggressive inclinations of other men (Sell et al. 2009, 2010) and actively assess the likely outcomes of violent encounters between themselves and other men (Fox 1997). Today, the proliferation of sports undoubtedly developed as a constructive alternative for dealing with the proclivities of young males that evolved in a very different time. In a legally sanctioned gladiatorial arena, young men compete to exhibit the same skills – throwing, clubbing, running, wrestling, tackling, and eye-hand coordination – that would have made them successful fighters and hunters in the ancestral environment. The popular appeal of spectator sports, especially for men, probably occurs at

least in part because it taps into an innate interest in the physical capabilities of other men.

The idea that men use war as a way of competing with each other to impress women has clearly been around for quite some time. For example, the Sioux warrior *Rain in the Face* once commented on the fact that the presence of women in a war party caused his warriors to vie with one another more intensely in displaying their valor (Philbrick 2010).

What Are the Necessary Precursors to War?

In addition to the aforementioned prerequisite of having a sufficient number of young men in a group who are able to fight, evolutionary social scientists have long recognized that a number of other conditions predict a group’s willingness to wage war. (See Shackelford and Weekes-Shackelford (2012) for a comprehensive overview.)

For example, it is essential that armies marching into battle have clearly distinguished their “sympathy groups” (often overlapping with kin groups) from their enemies for whom they hold little or no sympathy. Ideologies and religion can facilitate this process by creating certainty about holding the moral high ground in a conflict, which bolsters both a strong ingroup identification and a callous disregard for the fate of outgroup members. A recent study indicates that individuals may be more likely to participate in a defensive war if clear benefits accrue to their group as a result of the war, but participation in offensive wars (i.e., one’s own group initiates the conflict by attacking another group) is more likely when the individual benefits personally from the war (Lopez 2017).

Because war is so costly and risky, for male psychology to have evolved a predisposition for going to war, several essential conditions must have been met. John Tooby and Leda Cosmides (2010) have identified four conditions that would be particularly important. First of all, successful soldiers must have greater sexual access to women than noncombatants. Secondly, coalitions

of fighters must believe that they will be victorious. Thirdly, the rewards that each warrior receives must be proportionate to the risks he has taken and the importance of his contributions. In other words, cheaters should never prosper. And finally, men going to war must not know for sure who will live and who will die; there must be a protective “veil of ignorance.”

Conclusion

Males have evolved adaptations for warfare over time because the benefits of displaying valor and genetic fitness by participating in war have outweighed the costs associated with such behavior. These adaptations include cognitive and coalitional predispositions that increase the effectiveness of violent, coordinated group behavior. In short, going to war in general and displaying war heroism in particular may be a way for males to advertise desirable personal qualities that enhance status and increase the likelihood that they will be chosen as a mate or an ally and be positioned for access to future resources.

War More Likely with Higher Likelihood of Success

Mark W. Allen
California State Polytechnic University,
Pomona, CA, USA

Synonyms

Coalitional aggression; Intergroup conflict; Theory of war; War

Definition

Evolutionary explanations for war posit that coalitional aggression against external social groups resulted in higher fitness over the long duration of the Pleistocene. The essential

challenge of these models is to account for the selection for such risky behavior given the potentially high costs to participants in attacks. This entry focuses on one influential hypothesis developed from this body of theory: that war is more likely with higher likelihood of success.

Introduction

The antiquity of warfare is a fundamental question for a wide variety of social science disciplines and an important factor in how conflict might be reduced in the future. Recent multidisciplinary research has provided abundant evidence that warfare has a long chronology, dating far back into the Pleistocene (Allen and Jones 2014; Bowles 2009; Gat 2017). While defensive warfare is readily understood as an adaptive behavior in the face of aggression, the initiation of offensive warfare requires a deeper analysis. Evolutionary models argue that members of hunter-gatherer groups accrued direct and indirect benefits (i.e., higher fitness) from joining unprovoked attacks against other groups, despite the potential risk of injury or death to participants (Wrangham and Glowacki 2012). The probability of a successful attack is a key “Darwinian algorithm” that confronted potential warriors over the long durée of the Pleistocene (Tooby and Cosmides 1988). An important point to consider is that both individuals and groups often chose (and continue to choose) poorly when making this calculation. Common causes for such miscalculation are overconfidence, positive illusions, and military incompetence (Johnson et al. 2006).

The Risk Contract of War

The risk contract of war model developed by Tooby and Cosmides (1988) is a cornerstone of coalitional aggression and the evolutionary psychology of warfare. They argue that a stable contract, to be a “psychologically imposed structure,” must reward or punish coalition members in proportion to their risks taken and their contributions to offensive actions.

Tooby and Cosmides (1988:6) posit that:

It can be shown that given 1) certainty of victory, 2) the assurance of a random distribution of risk of death among participants, 3) the assurance of a relatively “fair” allocation of the benefits of victory, and 4) efficiency in the utilization of reproductive resources on a zero-sum basis, *selection will favor participation in the coalitional aggression regardless of the existence or even the level of mortality (within broad limits)* (emphasis original).

The risk contract is thus a “Darwinian algorithm” that predicts that males will risk warfare in situations where the average fitness favors participation in coalitional aggression. Sex differences are predicted in this model since “females have more to lose, and less to gain, and such differences in consequences should be reflected in psychological sex differences in attitudes towards coalition formation and coalition-based aggression” (Tooby and Cosmides 1988:6).

Tooby and Cosmides point to the importance of numerical superiority being a key factor in predicting success. This in turn would strongly favor active recruitment and enforcement of coalitional participation, particularly by individuals with strong incentives for coalitional aggression (Gavrilets and Fortunato 2014).

Offensive Versus Defensive Warfare

Military science thinkers, from Sun Tzu to Clausewitz, stress the difference between offensive and defensive actions. The chief advantages of offense are the element of surprise and the ability to choose the timing and locations of engagements, but less widely recognized is that these pluses can be blunted significantly by the primacy of defense (Allen 2008). Moreover, failed attacks can also mean severe losses for routed invaders. Prudent offensive military operations are thus those with a high probability of success. The strategic logic of military science is thus congruent with the risk contract evolutionary model.

Evolutionary approaches to coalitional aggression also recognize differences between offensive and defensive warfare. An evolutionary explanation for defense against an unprovoked attack

is very straightforward, as attacked pacifists who turn the other cheek are not likely to enjoy increased fitness. It is unprovoked aggression that requires more complex calculations of costs and benefits (Rusch 2014, Tooby and Cosmides 1988).

Nobody’s Perfect: Overconfidence, Positive Illusions, and Military Incompetence

Evolutionary models of coalitional aggression must take account of another significant factor: miscalculation of the probability of attack success. Military history as well as a wide range of human competitions bear witness that aggressions initiated with a high expectation of success often nevertheless backfire spectacularly. Three factors are commonly posited in evolutionary approaches to account for miscalculation: overconfidence, positive illusions, and military incompetence (Johnson et al. 2006, Wrangham 1999). Overconfidence and positive illusions are common human tendencies to self-aggrandize, unrealistic expectations to control situations, and a sense of invulnerability. Military incompetence is exhibited when a force loses a conflict which they expected to win due to overconfidence, underestimating opponents, ignored information, or misallocation of resources. While these would appear to be maladaptive, they could all still be selected for over the long run if they provide an overall increase in average fitness despite even high casualty rates (Tooby and Cosmides 1988). Research by Johnson et al. (2006) suggests that males are more likely than females to fall prey to overconfidence, and that they are more likely to pursue coalitional aggression.

Conclusion

The origins of warfare is more than just an academic question. A better understanding of the causes of war may well be essential for current and future attempts to reduce its likelihood or severity. Evolutionary explanations such as the

risk contract model provide plausible mechanisms to account for the wide variety of evidence that warfare has ancient roots in even small-scale hunter-gatherer societies. Observations and theoretical arguments that war is more likely when there is a high probability of success appear to be parsimonious with available evidence as well as the tactical logic of military science.

Wason (1966) Selection Task

Ken Manktelow
University of Wolverhampton, Wolverhampton,
UK

Synonyms

[The four-card problem](#); [The Wason selection task](#); [Wason’s four-card problem](#); [Wason’s selection task](#)

Definition

The Wason (1966) selection task is a reasoning task based on the logic of conditional rules and their violation.

Wason’s selection task is a problem designed to explore the ways people reason with conditional statements, those that can be expressed using “if.” It is one of a suite of reasoning problems invented by the British psychologist Peter Wason (1924–2003) and arose from his interest in, and curiosity about, firstly, the use of conditionals in both everyday and official language and, secondly, a tendency he had uncovered in earlier research using another of his tasks for people to confirm their beliefs rather than test them through attempted falsification. (This story is detailed in Wason and Johnson-Laird 1972, a monograph reviewing the authors’ early work on reasoning.) Wason (1964) had previously observed that experimental participants did not adhere to the prescriptions of formal logic when drawing inferences from conditional statements.

The selection task made its debut in a book chapter (Wason 1966) and was quickly taken up by researchers around the world: in 1974, a whole conference on it was held in Italy, and it is now

common to refer to it as the most, or one of the most, often-used experimental paradigms in the field, “the mother of all reasoning tasks,” in the words of Stenning and van Lambalgen (2008, p. 44). The reason for the explosion in its popularity is captured in the title of a paper by Wason, reviewing his early findings: Structural simplicity and psychological complexity (Wason 1969). In the first published refereed paper on the task, Wason (1968) presented it in the following form. Four cards (real cards in those days; now, presentation is almost always computer-mediated) were placed on a table, and the participants were told that each one had a letter on one side and a number on the other (see Fig. 1). They were given the following sentence relating to these four cards: *If there is a D on one side of any card, then there is a 3 on its other side*. Their task was to decide which of the cards would enable them to determine whether the sentence was true or false; the experimenter, Wason himself in this case, pointed to each one and asked whether knowing what was on the other side would enable them to make that judgment.

There is a normative solution to this problem, deriving from standard propositional logic, to which human performance can be compared. We can use symbols to explicate this. Firstly, the sentence can be written in the general form *If p then q*; p is known as the antecedent part, q stands for the consequent. Secondly, assume that the target sentence is an implication conditional, i.e., one where, given the sentence’s truth, q necessarily follows from p, but the reverse – p from q – does not necessarily follow. There are thus two logically valid inferences from an implication conditional: p therefore q and not-q therefore

Wason (1966) Selection Task, Fig. 1 The standard abstract selection task cards, from Wason (1968). Below are their logical values; these were not shown when the task was presented. The target rule was *If there is a D [p] on one side of any card, then there is a 3 [q] on the other side*

not-p. The selection task is therefore asking participants to find those cards that could lead to valid inferences; in addition, they have to appreciate the need to try to falsify the statement, since a potentially falsifying instance provides a decisive test of its truth. The only valid falsifying instance is p with not-q, since such a combination violates the two valid inferences. Using the materials in the 1968 example above and in Fig. 1, there are two cards which could lead to falsifying instances: the D (i.e., p) card, which could have a number other than 3 (i.e., not-q) on its reverse, and the 7 card, because 7 is not 3 (i.e., not-q) and so would falsify if it had a D on its reverse. The other two cards need not be examined since neither could bear the falsifying p, not-q combination.

Human Performance in the Early Days

The normative solution to the selection task is to select the p and the not-q cards and ignore the not-p and q cards, but in Wason's original experiment, only one of his 34 participants did so; the modal selections were for the p card alone or the p and q cards. Thus they tend always to select the p card and hardly ever to select the not-q card. In now over half a century of research featuring this basic version of the task, involving hundreds of experiments around the world, these essential findings have stayed the same. It is a very robust paradigm. Much effort has been expended in trying to solve the riddle of the psychological complexity of the selection task (see Manktelow 2012, for a fairly recent summary), but for present purposes, that is largely beside the point. Its interest lies in the uses to which it has been turned, and its robustness has made it into a kind of cognitive recording electrode, which can be used to probe a number of functions. One of these was as a test-bed for hypotheses derived from evolutionary theory.

An obvious ecological objection to the task in the form in which it was first used in experiments, using what came to be known as abstract materials, is to its artificiality: testing cards for letter-number (or other symbolic) combinations bears scant resemblance to the kind of thinking

conducted in real life. The equally obvious remedy is to reengineer it to be more realistic. This was done by Wason and Shapiro (1971). They presented the task as a claim about journeys, with four cards showing four days' journeys, the destinations on one side and the means of transport on the other. The target sentence was *Every time I go to Manchester I travel by car*, and the cards showed Manchester (p), Leeds (not-p), Car (q), and Train (not-q). Which cards need to be examined to tell whether the stated claim is true or false? Manchester, in case I used some other means to get there, and Train, in case I went to Manchester on it; these cases would falsify the conditional claim. Ten of the 16 participants given this version chose this p, not-q combination, compared to 2 out of 16 given a letter-number version.

Unlike results with the basic version, this finding has not proved stable; simply using realistic content does not necessarily facilitate logical performance. It has to be a particular kind of realistic content to facilitate reliably: *deontic* content, that is, content containing rules stated as regulations, not generalizations. This was discovered, but not initially recognized as such, by Johnson-Laird et al. (1972), who reported a record-breaking facilitation effect using materials relating to a postal sorting scenario. Participants were told to imagine they were mail sorters, given the rule *If a letter is sealed, then it has a 50c stamp on it*. The selection task cards were envelopes, showing a sealed one (p), an unsealed one (not-p), one with a 50c stamp (q), and one with a 40c stamp (not-q). The participants had to choose those to examine "to find out whether or not they violate the rule" (Johnson-Laird et al. 1972, p. 397). Twenty-one out of 24 participants chose the correct pair, the sealed envelope (which might have an inadequate stamp) and the 40c envelope (in case it was sealed); only 2 of 24 did so in an abstract condition. Johnson-Laird et al. explained this effect as being due to the postal materials "lead[ing] the subject to a greater insight into the logical structure of the task" (p. 396). This explanation was undermined by subsequent research, which showed that the postal task was tapping into a form of reasoning categorically different from that called for by the abstract task or

thematic versions such as the “journeys” task: deontic reasoning. In retrospect, there were clues in the postal version’s materials; they were not just realistic, but realistic in a particular way. For a start, the target conditional was a rule in the sense of a regulation, a statement designed to control behavior; it was not an indicative claim about factual possibilities. Secondly, following on from this, there is an implied modal term in the consequent: sealed letters *must* have a higher valued stamp. This is not the case with indicative, descriptive claims. Finally, the participants were not instructed to test its truth, but to detect possible violations. A violation of a regulation does not render that rule false, as any police officer will affirm.

Evolutionary Psychology and the Selection Task

“Deontic” is a term co-opted from philosophy and denotes thinking associated with obligations (of which the postal rule is an example), permissions, and so on. Deontic reasoning is thus the kind of reasoning we perform when considering what we should or should not, or may or may not, do. The first research to test directly the proposal that tasks such as the Johnson-Laird et al. postal task were evoking deontic rather than indicative reasoning was reported by Cheng and Holyoak (1985). Their work eliminated an early competitor to Johnson-Laird et al.’s original “insight” explanation: the memory-cueing hypothesis of Manktelow and Evans (1979; also Griggs and Cox 1982). This amounted to a proposal that the participants’ familiarity with the content of the postal task meant that they were not reasoning at all, but simply recalling their real-world knowledge.

Griggs and Cox had found that there was no facilitation when the postal task was run in Florida, USA, where there had never been a two-tier stamping rule (the original task had been run in Britain, which had had just such a rule), whereas a drinking-age rule, with which the Florida population was familiar, did produce facilitation. Cheng and Holyoak also gave US

participants a postal selection task but in the instructions gave explicit information about the costs and benefits to the postal service and its customers: the service charged more for sealed mail to increase profits, and the customer had to pay this surcharge for personal mail if they wanted it sealed. With this rationale, both US and Hong Kong participants produced high levels of p, not-q selections; without it, the Hong Kong group’s performance stayed high, while the US group’s was significantly lower; Hong Kong had had a two-tier stamping rule, so it was familiar to them but not to the US population. Cheng and Holyoak proposed that deontic facilitation occurred through the invocation of *pragmatic reasoning schemas*. These, they argued, were packets of knowledge about what to think and do, instantiated as a set of production rules, such as *If an action is to be taken, then the precondition must be satisfied*. When a task scenario maps on to one of these rules, as the postal task does with this one, the schema is invoked, and the necessary inferences are generated. They gave this a strong test by the novel tactic of using an abstract deontic task, which removes any question of mere familiarity: here, the target rule was *If one is to take action A, then one must first satisfy precondition P*. The cards showed “Has taken action A” (p), “Has not taken action A” (not-p), “Has fulfilled precondition P” (q), and “Has not fulfilled precondition P” (not-q). Significantly more p, not-q cards were selected with this task compared to a non-deontic abstract version.

According to Cheng and Holyoak (1985), people reason “using abstract knowledge structures induced from ordinary life experiences” (p. 395). However, it is possible that the source of these knowledge structures is more fundamental than that: that they are part of humans’ evolutionary endowment. This was the possibility addressed by Cosmides, in a hugely influential paper published in 1989. Cosmides introduced to the psychology of reasoning what has come to be known as *social contract theory*. It was based on the evolutionary theory of reciprocal altruism, put forward by Trivers (1971) to explain the evolution of cooperation in social situations: organisms initially incur a cost to themselves to provide a benefit to others,

Wason (1966) Selection Task, Fig. 2 Cards in the basic version used in the social contract experiments of Cosmides (1989), with logical values (not presented to participants) below. The target rule was *If a man eats cassava root [p], then he has a tattoo on his face [q]*

a rational strategy providing there is a well-founded expectation that the same will be returned to them.

Cosmides refined this dynamic into a set of what she called Darwinian algorithms. The basic rule of social exchange in this scheme is a conditional: *If you take a benefit, then you pay a cost*. This rule is not sufficient in itself for efficient social exchange: it has to be policed, for there is a powerful incentive to cheat, to take the benefit without paying the cost; any organism that can get away with this is at an advantage compared to those which comply with the rule. Cosmides therefore added a cheater-detector algorithm, a cheater being someone who takes the benefit without paying the cost. Cosmides' theory thus inherits the benefit-cost component from Cheng and Holyoak's but, unlike them, proposes that Darwinian algorithms are an evolved capacity, not a product of learning.

Cosmides (1989) claimed that all reliably facilitating versions in the selection task literature could be fitted to her scheme and went on to test it using novel contents. Her experiments generally concerned imaginary anthropological expeditions studying native people in remote locations, making observations of their cultures stated in the form of conditional rules. An example is *If a man eats cassava root, then he has a tattoo on his face*. Cassava was presented as a highly desirable commodity (a powerful aphrodisiac) available only to married men, marital status being signified by the tattoo. Thus the benefit is cassava, the cost is getting married (and tattooed). She constructed selection tasks wherein the familiar four cards read Eats cassava root (p), Eats molo nuts (not-p), Has tattoo (q), Has no tattoo (not-q;

see Fig. 2). This task can then be framed as a deontic, cheater-detection task, or as an indicative, test-the-claim task. The predicted facilitation of p, not-q selections with the deontic version was duly observed.

Cosmides then mounted a strong test of the theory: she used "switched" social contract rules, this time reading *If you pay a cost, then you take a benefit*; e.g., *If a man has a tattoo, then he eats cassava*. A cheater in this condition is still one who takes the benefit (cassava) without paying the cost (tattoo), but in selection task terms, these are now the not-p, q values, the opposite of the standard logical indicative solution. Selection of not-p, q items had never been predicted before, but was produced by 70% of Cosmides' participants in this condition; close to zero did so with an indicative task.

This paper was followed by a host of experimental studies and theoretical discussions. These both divide into two categories: criticisms of or extensions to the social contract theory. An early critical study was reported by Manktelow and Over (1990; see also Cheng and Holyoak 1989), who devised a deontic but nonsocial contract version that still facilitated "logical" selection task responses. It concerned the behavior of nurses who were given the rule, *If you clear up spilt blood, then you must wear rubber gloves*. Cards showed the records of four nurses, with whether or not they cleared up spilled blood on one side and whether or not they had worn rubber gloves on the other. A violator of this rule is clearly one who clears up blood without wearing gloves, i.e., p, not-q, and three-quarters of the participants chose this pair of cards. But the rule is not one of social exchange: blood is not a

benefit for which gloves are the cost. Cosmides' response was to argue that this rule tapped into a different set of Darwinian algorithms, in this case a hazard management schema (Fiddick et al. 2000). Fiddick went on to produce converging evidence for such a schema, and its distinction from social exchange, using paradigms other than the selection task (e.g., Fiddick 2004).

Thus what started as a critical study was turned by social contract theorists into an extension. Further studies have also done this. Hiraishi and Hasegawa (2001) used the selection task to study "free riders" – cheaters, in other words – from a group perspective. Resources tend to be shared among in-group members, and denied to out-group members, in many social species, including humans. Two forms of violation, failure to share within the group and exploitation of the group's resources by nonmembers, should be detectable, and Hiraishi and Hasegawa found evidence, using a selection task with the target rule *If one receives a resource, one is an in-group member*, for both; the effect was strongest when out-group exploitation was in question. Similarly, Brown and Moore (2000), changing the focus from cheaters, used selection tasks to show that people are adept at detecting pure altruists: those who provide benefits to others but seek nothing in return.

An instinct for effective social contract reasoning implies something else: that it should appear early in child development, since its innateness makes it, at least to some degree, independent of experience. This hypothesis was strikingly confirmed by Cummins (1996). She derived the prediction not from social contract theory, but from another evolutionary concern: the construct of dominance hierarchies. She argued that there is an innate capacity for deontic reasoning based on what is permitted, prohibited, or obligated given one's position in a hierarchy. Adapting a modified, highly concrete version of the selection task introduced by Girotto et al. (1989), she presented it to children as young as 3. Instead of cards, these children were given materials consisting of a toy cat and toy mice, together with a mouse house. Some of the mice squeaked when squeezed, some did not. The children were told that the queen

mouse had laid down a rule because of the danger from the cat: *It is not safe outside for the squeaky mice, so all squeaky mice must stay in the house*. Which mice should be tested (squeezed) to see whether they were breaking the rule? Over two-thirds of the 3-year-olds correctly chose the ones outside the house, to see if they were squeakers.

Both the pragmatic reasoning schema theory and the social contract theory emphasized the cost-benefit relations inherent in the versions of the selection tasks they employed. Both theories are modular, especially so in the case of social contract theory, based as it is on the foundational construct of capacities that have evolved through time to enable adaptation to particular environmental contingencies. The distinction between social contract and hazard management explanations of responses to different task contents was an illustration of this modularity. However, cost-benefit relations are also fundamental to a non-modular theory: decision theory. This approach was adopted by Manktelow and Over (1991), who used it to predict not-p, q selections – something only ever previously predicted and observed by Cosmides with switched rules – with non-switched rules. Cheating, in Cosmides' terms, can be bi-directional: you can cheat someone, or they can cheat you. Manktelow and Over used the rule, *If you tidy your room, then you may go out to play*, said to have been spoken by a parent to a child. The effectiveness of such a rule depends on the subjective utilities (perceived benefits and costs) for each party and the parties' mutual understanding of them. The parent violates the rule when she does not let the child out even though he has tidied his room (p, not-q), but she also goes wrong when she lets him out even though he hasn't tidied up (not-p, q); the child violates the rule when he goes out without having tidied his room (not-p, q) and also when he does not go out even when he has (p, not-q). All four such patterns were observed in selection tasks.

Bi-directional violation of deontic rules is not the sole preserve of utility theorists: it was predicted by social contract theorists such as Gigerenzer and Hug (1992), who called it a social perspective effect, the name by which it came to be known. However, Gigerenzer and Hug tested

only two of the four possible cases outlined above, where the authority (the parent in the example; they used different contents) denies the benefit even though the cost has been paid and where the subordinate (the child) takes the benefit without paying the cost; these are the cases predicted by social contract theory. It is not clear how the theory would predict the other two cases, which appear to be instances of weakness or self-denial. Further utility-based studies have included probabilistic components in the materials, since decision theory is based on the notion of subjective expected utility, and this variable has also been found to have an effect (e.g., Kirby 1994; Manktelow et al. 1995). Once again, it is not clear how this would be predicted by any schema theory, evolutionarily based or not, since transgression would appear to be an all-or-none matter: an action is either taken or it is not; a precondition is either met or not met. Much of this and the ensuing debate was set out in a volume edited by Over (2003), which includes contributions from protagonists of all positions.

Conclusion

Periodic obituaries for the Wason selection task appear in the reasoning literature from time to time, often making two points: that it has been mined out now and that it was a slightly trivial task in the first place anyway (see, e.g., Cohen 1981; O'Brien 1995; Sperber et al. 1995 for examples from many years ago). Both objections are misplaced; reports of its demise have always, like Mark Twain's, proved an exaggeration. It has provided the base for serious theoretical advances in both evolutionary psychology and the psychology of reasoning and for 30 years of continuing experimentation and theoretical debate thereafter. And not just in this area; research in the 1970s was among the earliest to give rise to the now highly influential dual-system theory of thought, for instance (Kahneman 2011; Wason and Evans 1975; Wason and Johnson-Laird 1970). It is not the task itself but the uses to which it can be put that have been profitable to psychological research and that can be expected to continue to be so.

Definition

A tool is something that helps you gain an end.

Introduction

While fish have recently received a lot of attention in comparative cognition studies, studies on tool use in fish are still scarce (Balcombe 2016; Brown et al. 2011; Bshary and Brown 2014). A big principal problem when trying to manipulate objects in their environment is that fish are more limited in terms of body appendices they can use than most nonaquatic animals. With fins, which are usually not capable of grasping or holding an object, the mouth becomes to foremost contact and interaction point to the outside world. However, the density of the medium makes using the medium itself to manipulate or move objects much more efficient and possible than in a terrestrial environment. Still this leads to another obstacle one encounters in the study of tool use in its definition. If we stick to one of the classic definitions of tool use which is to modify one object or item or agent in order to achieve an effect on another (Beck 1980), then there are several compelling examples of tool use in fish. Thus, the use of water – by directing a waterspout at an object or a prey item – has thus been considered tool use by several authors.

Using Waterspouts as Tools

As the surrounding milieu of fish is much denser and heavier than the medium surrounding terrestrial animals, different types of manipulation of objects become easier or harder. While air puffs on land will be of limited success to move larger objects or a larger amount of material – e.g., clearing sand, waterspouts allow both for clearing spaces and moving objects and for predation. The most well-known example of the usage of waterspouts is certainly the archerfish. There is a multitude of studies showing the ability of this fish to use waterspouts to prey on arthropods outside the water. The fish can even be trained to use these waterspouts to shoot at specific targets in cognitive learning experiments (Newport et al. 2016).

But archerfish are not the only fish using waterspouts to achieve goals. Among many others, triggerfish and also wrasses use waterspouts to move or uncover previously hidden food items. The same has been observed in cartilaginous fish. Both rays and sharks blow water into sand to uncover hidden food items. So far the animals' ability to adapt this strategy to an experimental setup has been tested in freshwater stingrays (Kuba et al. 2010). In the first study on possible tool use in freshwater stingrays (Kuba et al. 2010), researchers showed that the rays can manipulate the surrounding milieu – water – to retrieve food from a tube-shaped testing apparatus. Interestingly they were more likely to use water suction than waterspouts to retrieve food from a pipe-shaped feeding apparatus. This was achieved by using both their disc-shaped body to cover one exit of the tube while performing undulating fin movements to create a flow through the pipe toward the moth. Once the animal was experienced in this procedure, it most likely combined this technique with sucking movements of the moth to achieve a fast retrieval of the food reward.

Using Innate Objects as Tools

A recent study on cod (Milot et al. 2014) claimed that fish, which learned to use a rope connected to a feeder, exhibited tool use. While this has been

debated, it is clear that the potential plasticity of the behavioral modification of fish behaviors deserves attention. Although, it might be that pulling the string may not be the equivalent to a classic lever pulling experiment, it is still remarkable that the fish do understand that there is a relationship between the manipulation of one object, a rope, and the arrival of food.

Some of the most compelling examples for tool use in fish show wrasses, a rather modern group of fish, using waterspouts to uncover food and then various hard surfaces to open the food (Bernardi 2012). In essence several studies showed that different species of wrasses pick up a clam hidden in the sand and transport them to a rock (anvil). They then smash the clam against the rock surface in order to break it (Coyer 1995; Jones et al. 2011; Pasko 2010).

Conclusion

With all these examples of tool use or proto-tool use, it seems fair to conclude that fish deserve more attention when it comes to comparative studies on cognitive behaviors and the evolution of intelligence. The difficulty of all these studies remains that tool use in fish is inherently different, as the potential body parts used to manipulate objects, primarily the mouth, differ from what we observe in terrestrial species. Additionally, holding an object in the mouth in order to produce food carries the distinct disadvantage that any object needs to be dropped before food can be consumed. In general we know far too little on object interaction and manipulation in fish. It would be of great interest to study tool use also in combination of exploration of novel objects and maybe even object play. Taking all this into account, the present examples provide a fascinating glimpse and an important starting point for further studies, both in the field and in the laboratory.

Weaning

Deborah Kimminau

Northern Illinois University, DeKalb, IL, USA

Synonyms

[Gradually deprive of mother's milk](#)

Definition

Weaning begins the moment a child consumes a source of nutrients other than breastmilk. Weaning ends after the child consumes breastmilk for the last time. Weaning, then, can be defined as the process that occurs between this beginning and end.

Introduction

The weaning process may take many forms and vary greatly in length of time to complete. There are two distinct aspects of weaning: (a) weaning the child from the breast to other sources of nutrients and (b) weaning the child from the breast as a source of comfort and nurturance. These aspects can be challenging to disentangle during the weaning process.

Another question concerns whether a child is weaning from the breast or from breastmilk. When a mother cannot nurse her infant at her breast, she may express her milk and feed the child using a bottle. In these cases, weaning is concerned primarily with transferring the child to other sources of nutrients, possibly substituting infant formula for breastmilk in the bottle. Though a bottle also can be a source of comfort, it is not

considered breastfeeding and can be provided by someone other than the mother. The process of weaning a child from a bottle is not addressed here.

Process of Weaning

Weaning requires physical and psychological adjustments for both mother and child. For the child, other foods must replace the nutrition received in breastmilk. This is particularly challenging for younger infants, especially when access to nutritional foods is limited. In addition, the mother requires fewer calories after weaning and must adjust her diet accordingly.

From a psychological perspective, the mother-child dyad must find other means of soothing the child when needed. There may be a period of adjustment while this transition occurs. The mother may go through a personal transition when breastfeeding ends, sometimes involving a process of psychologically letting go of that unique period of the mother-child relationship and moving on to the next phase (Nelson 2006).

In addition, there are physical changes that occur for the mother when the child weans. The mother's breasts must return to a non-lactating state, requiring hormonal adjustments that may return the mother to a state of fertility (Kennedy 2005). Her experience of these changes depends upon the amount of milk being produced at the time of weaning, as well as how abruptly the weaning occurs.

Abrupt Weaning

Abrupt weaning happens suddenly and can be initiated either by the child or the mother. Abrupt weaning is difficult for both mother and child, physically and emotionally (Grueger 2013). It is rare for a child to initiate weaning abruptly, although there is a phenomenon known as a nursing strike, during which the child may refuse the breast. There are many possible reasons for such a strike, but it usually can be resolved and need not always signify the end of breastfeeding (Grueger 2013). A mother may need to wean suddenly due to unforeseen circumstances such

as illness or extreme difficulties in breastfeeding (Cooke et al. 2003; Grueger 2013). In either case, this will require other sources of nutrients and comfort for the child and will involve a potentially intense physical, hormonal, and psychological adjustment for the mother. The suddenness of this transition may lead to mastitis or other difficulties.

Gradual Weaning

Gradual weaning occurs over an extended time period. This is typically easier for both mother and child, as each has more time to adjust physically and psychologically to the transition. A child who is getting other nutritious foods and receiving comfort other than breastfeeding may simply breastfeed less frequently over time. This can happen naturally at a wide range of ages, most commonly between 2 and 4 years (Grueger 2013). The mother may initiate gradual weaning by emphasizing other food sources and providing other forms of comfort. Mothers may reduce the frequency of breastfeeding gradually, possibly using a schedule of feedings (Grueger 2013).

In situations of extended breastfeeding beyond 2 years, the experience of weaning may be somewhat different (Stearns 2011). Typically, the child is not breastfeeding as often, possibly only one to four times per day, and it may be primarily for comfort, such as when the child is tired, injured, or sick (Dettwyler 2004). Also, older children may get much of their nutrition from other sources. In these cases, weaning is less of a dietary transition and more of a transition in finding other means of comfort.

Timing of Weaning

As it is well-established that breastmilk provides superior nutrition and immune support for the child and health benefits to the mother (AAP 2012; WHO 2001), there are clear evolutionary advantages to the practice. It is less clear how long breastfeeding should continue. There are wide variations in the timing of weaning across cultures and historical periods. In some situations,

breastfeeding is an imperative upon which infant survival depends, while in others, breastfeeding is considered a voluntary decision (Nelson 2006). This variation, along with differences in cultural norms, personal beliefs, and maternal experiences of breastfeeding, causes a wide range in child age at time of weaning, from weaning at birth to weaning at age 7 years or beyond (Dettwyler 2004). The average age of weaning worldwide is 2.5 years (Kennedy 2005), but this average is misleading due to the many outliers, including many mothers who do not breastfeed at all (AAP 2012).

Current Recommendations

The American Academy of Pediatrics (AAP 2012) recommends exclusive breastfeeding (no other sources of nutrients) for the first 6 months of life. They further recommend continued breastfeeding while additional foods are introduced, until 1 year of age or longer, as desired by both mother and child (AAP 2012). The World Health Organization (2001) similarly recommends 6 months of exclusive breastfeeding followed by children receiving breastmilk and complementary foods up to 2 years or longer.

Historical and Cultural Variation

Ancient texts including both Koran and Bible recommend weaning at an average age of 2–3 years (Kennedy 2005). However, cultures vary widely. In the !Kung tribal culture, for example, infants nurse about four times per hour, delaying maternal fertility for several years, and wean at an average age of about 4 years (Kennedy 2005). In other cultures, the time of weaning may be influenced by many factors, including cultural beliefs about sex during breastfeeding, the form of maternal work, and the desired reproduction rate (Dettwyler 1995). Foraging cultures tend to wean slightly later than agricultural cultures (Kennedy 2005).

Especially in industrialized areas, the average age of weaning is earlier and does not match current recommendations (Karall et al. 2015; Nelson 2006). Some of this difference relates to

cultural views about breasts. While Western cultures view breasts as sexual organs, this is not true of most cultures, leading to varied beliefs about breastfeeding and weaning (Dettwyler 1995). In Mali, for example, breasts are viewed solely as feeding organs and are not covered (Dettwyler 1995). It is common to see these mothers breastfeeding in public places. Due to societal pressures, some mothers in Western cultures wean earlier than they would prefer (Stearns 2011). Others continue but hide their breastfeeding (Dettwyler 2004; Grueger 2013; Stearns 2011), leaving a misleading impression that extended breastfeeding is more unusual than it is.

In nonhuman species, weaning occurs as the juvenile becomes capable of finding its own sustenance independently (Kennedy 2005). In humans, children are weaned long before they can provide their own food. To remove the cultural biases regarding weaning, Dettwyler (2004) studied an array of variables in other primates that might suggest the natural time of weaning. For various primate species, weaning age can be predicted by variables including body weight attained, eruption of first molars, length of gestation, and age of first breeding for females. Considering these variables from a human perspective suggests a natural time of human weaning between 2.5 and 7 years (Dettwyler 2004).

Benefits of Early Weaning

There are many reasons a mother might wean before the recommended time. Common reasons are a sense of producing insufficient milk, low feelings of breastfeeding self-efficacy, and breastfeeding difficulties (Karall et al. 2015). Other reasons might include convenience for returning to work or resuming other duties, a preference to work toward a specific schedule, or a desire for more assistance with feeding. There are no documented benefits to the infant for early weaning, except in unusual circumstances in which breastfeeding would be unsafe due to infectious disease or specific medications or drugs (AAP 2012). With some diseases, the breastmilk

is still safe and can be expressed and fed with a bottle.

Benefits of Later Weaning

There are also many reasons a mother might wean later, including health benefits to the child, a desire for a close mother-child bond, and a sense of satisfaction in watching the infant thrive (Nelson 2006). Distinct health benefits have been demonstrated with longer breastfeeding. Exclusive breastfeeding for at least 6 months correlates with reduced gastrointestinal and respiratory infections in the child and delayed fertility for the mother (WHO 2001). Later weaning correlates with reduced risks of child allergies, leukemia, pneumonia, and obesity (AAP 2012). For the mother, increased cumulative time of breastfeeding is correlated with reduced risks of breast cancer, ovarian cancer, diabetes, rheumatoid arthritis, cardiovascular diseases, and postpartum depression (AAP 2012).

Evolutionary Perspective

Kennedy (2005) states that from an evolutionary perspective, the timing of weaning presents a dilemma. While later weaning increases the chances of offspring survival and improves the health of both mother and child, it also delays fertility, decreasing the potential for overall population growth. Pregnancies spaced closer together increase the number of offspring but correlate with reduced survival for both children, while later weaning allows the mother to focus on the needs of one child.

Dettwyler (1995) describes three main evolutionary benefits of breastfeeding which appear to favor later weaning. First, there are health benefits to both mother and child for the duration of breastfeeding, increasing the long-term survival rates of both. Second, hormones released during breastfeeding promote affectionate maternal feelings and facilitate nurturing behavior, increasing both child survival rates and the mother's likelihood to continue to nurse for a longer period. Finally, the delayed ovulation resulting from frequent breastfeeding increases the spacing between children, improving child and mother survival

rates, potentially increasing the number of the mother's children who will survive into adulthood.

Support for Breastfeeding and Weaning

Many mothers lack breastfeeding support due to lack of family and friends with breastfeeding experience, and this may lead to earlier weaning (Nelson 2006; Dettwyler 1995). For example, some mothers experience breastfeeding difficulties related to poor infant attachment to the breast (Cooke et al. 2003) or worry about insufficient milk production (Karall et al. 2015). Such problems may lead to early weaning but often can be rectified if mothers have adequate breastfeeding knowledge and support. Mothers also may need support during the weaning process.

If support is not available from family or friends, support can be found through lactation consultants, who are specialists in breastfeeding issues. In addition, free support can be obtained through La Leche League International, a worldwide mother-to-mother support organization. Finally, some pediatricians can be helpful, though not all have expertise in this area.

Conclusion

Just as breastfeeding is a personal journey for the mother and child, each experience of weaning is unique to the parent-child dyad (Nelson 2006). The process of weaning itself, as well as the physical and emotional experience of it, will vary dramatically based on a variety of factors that include personal and cultural factors, the age of the child, the frequency of breastfeeding, and the family dynamic. The timing of weaning is likewise varied, though from an evolutionary perspective, later weaning (at least 2.5 years) seems to favor longer survival of both mother and child. Interestingly, despite significant variation in age of weaning across culture and history, ancient texts suggest weaning at 2–3 years of age, which remains the average current weaning age worldwide.

Weaning and Maternal-Fetal Conflict

Jennifer Kotler

Harvard University, Boston, MA, USA

Synonyms

[Nutritional independence](#); [To stop nursing](#)

Definition

The decrease in milk provisioning by a mother to her offspring; a young mammal's shift to nutritional independence in the form of food instead of mother's milk.

Introduction

Evolutionary conflict occurs when natural selection acts in opposing directions on different genes involved in an interaction (Burt and Trivers 2008). Conflict can be found at all levels of organization, from conflict between species to conflict between individuals within a species to conflict within an individual itself. Most of these forms of conflict revolve around competition for resources and differences in optimal resource allocation among individuals. Between genetic relatives, what is beneficial to one relative may not be beneficial, and may even be detrimental, to another. This situation occurs when there is an unequal probability that genes from one individual will be shared with another. For example, if a mother invests abundant resources in one child, it benefits both that child and, due to shared genes, the mother herself; however, it will detract from the mother's ability to invest in other offspring. From the maternal perspective, she shares half her genes with each of her children, so she benefits optimally from maximizing her reproductive output. However, from the perspective of any one child, there is a lower probability that a gene found in that child's genome will be present in other

siblings (although there is a 50 % probability that a maternal gene found in one sibling will be found in the other, the sibs may not be paternally related, thereby reducing their probability of genetic similarity) (Trivers 1974). Therefore there is an unequal benefit for the child relative to the mother when she allocates resources to any one child versus conserving resources for other potential offspring. These situations produce what is known as maternal-offspring conflict.

While the placenta is the only source of nutrient exchange throughout fetal development, the breast takes over as the primary source of nutrition after birth. This marks a power shift from the fetus (which is able to directly influence maternal biology in utero) to the mother, who is now better able to control the amount of investment she dedicates to each offspring. A major point of maternal-offspring conflict occurs at the time of weaning. It is in mother's best interest to wean early enough to fit in another reproductive event, while baby would gain more benefits from exclusive access to maternal care at a potential cost to future maternal sibs (Haig 2010). Weaning is an exemplary instance of this form of conflict: weaning allows mum to exit lactational amenorrhea (infertility during breastfeeding) and increase her likelihood of having another child, while it directly withdraws calories from baby forcing it to become nutritionally independent.

Weaning in Primates

Across primates the strongest behavioral examples of maternal rejection occur at the time of weaning. In a study of gelada baboons, maternal rejection was more frequent during feeding than at any other time, including socializing, moving, or resting. Furthermore, as the infant aged, feeding rejections increased steadily, while rejections during other activities stayed fairly consistent over time (Maestripieri 2002). From mum's perspective, nursing becomes more expensive as the nutritional demands of the offspring continue to increase. Furthermore, nursing an infant impedes a mother's ability to have another offspring (Haig 2014). At the same time, there is evidence across

mammals that prolonging nursing can have positive effects for the infant, including increased body weight, decreased parasite load, enhanced immune system, and decreased infant mortality (Mandalaywala et al. 2014).

Now that the baby is largely unable to interfere with maternal physiology, the biggest tool at its disposal is psychological. Immediately after birth the newborn mammal is completely dependent on mother for all nutritional needs. That being said, baby can perform certain behaviors to increase the likelihood of eliciting maternal care. These include making eye contact, smiling, and crying (Als 1977). In fact, crying and screaming have been correlated with increased time at the nipple across all age categories, showing that this is a fairly effective strategy for a hungry infant to employ (Maestripieri 2002). In Rhesus macaques once a mother has been experimentally separated from her offspring, the infant will cling to her upon her return, even in the face of more explicit maternal rejection (Trivers 1974). This appears to be a specific response to maternally initiated absences, since the same behavior is not seen if the infant is removed and the mother is left in the home cage. This suggests an adaptive response by the infant in response to cues of retracted maternal care. A variety of primate infants show behavioral regression after maternal rejection, including whimpering, ventral riding, and prolonged maternal contact; this behavior is intensified with the onset of maternal remating (Horvat and Kraemer 1982; Maestripieri 2002).

Time of Weaning in Humans

While the period of human childhood is typically much longer than in other primates, humans wean significantly earlier than most other great apes, and with some unique characteristics (Kennedy 2005). While human mothers tend to wean infants off the breast at around 2 years, there is a prolonged period of nutritional dependency that can last for the next 15 years or more, whereby the offspring is still largely dependent on maternal or allomaternal food provisioning (Van Noordwijk et al. 2013). One explanation for this phenomenon involves maternal-offspring conflict: early

weaning is a maternal strategy to increase maternal fitness at a cost to offspring fitness, while increased offspring demands via an extended period of nutritional dependency increase the offspring's fitness at a cost to the mother (Haig 2010). Support for this hypothesis can be found in our genes. While genes found in the mother have a 50 % chance of being found in this and future offspring, this probability is lower for genes found in the father. Over evolutionary time this has resulted in differential expression of certain paternally and maternally inherited genes in a way that reflects this inequality. Evidence of this can be found in various paternally expressed (maternally silenced) genes, which favor increased and more intense suckling (Haig and Wharton 2003). Maternally expressed genes, on the other hand, seem to favor earlier maturation (Haig 2010). It has been theorized that this allows human mothers to decrease their interbirth intervals (IBI) more than other great ape mothers can, resulting in overlapping generations of offspring (Haig 2010). That is to say, a human mother can have two children (one on the breast and one who is weaned but remains nutritionally dependent) in the same amount of time as it takes other great apes to wean a single offspring (Kennedy 2005). However, this decreased IBI comes at a cost to the first offspring, who now has to share maternal resources with a new baby (Haig 2014). It appears that human babies may have adapted some particular defenses in response. Human infants that are breast fed appear to cry more during the night than infants who are weaned or formula fed, even in cultures where mothers and baby sleep in the same bed (Haig 2014). Since they are receiving the same number of calories, it is likely that the cause of this sleep disruption is not due to hunger, but rather because natural selection has favored babies who are better able to delay conception of a new sibling through suppressed ovarian function and increased maternal fatigue.

Conclusion

Nursing is an important part of mother-offspring bonding and a necessity for the survival of primate infants. However, the costs and benefits of

prolonged nursing are different from the perspective of the mother and the child. Over time, this has resulted in a tug-of-war, with adaptations in mothers for reduced nursing costs and earlier weaning and adaptations in offspring for increased breast milk availability. In humans, this has been extended to reflect the decreased IBIs and overlapping generations present in human families.

Westermarck Effect

Jan Antfolk and Helena Godenhjelm
Department of Psychology, Åbo Akademi
University, Turku, Finland

Synonyms

Incest aversion; Kin-recognition; Negative sexual imprinting

Definition

The decreased sexual interest between individuals who have co-resided in childhood.

Introduction

In his seminal book, *The History of Human Marriage* (1891), the Finnish sociologist and philosopher Edward Alexander Westermarck provided an evolutionary explanation for the evident lack of sexual interest between close kin. Deeply inspired by both Charles Darwin and Alfred Russel Wallace, Westermarck, who was looking to solve the question regarding the cross-cultural incest taboo, proposed that “there is an innate aversion to sexual intercourse between persons living very closely together from early youth, and that, as such persons are in most cases related, this feeling displays itself as a horror of intercourse between near kin” (Westermarck 1891, p. 321). Westermarck further argued that during the course of evolution, innate aversion had developed through natural selection: “[T]his instinct developed through natural selection. We cannot

give away to carnal love with those [...] to whom we generally stand as siblings, parents, or children; since each such passion must have gone extinct in our species’ childhood through the increased mortality to which offspring from closely related parents are subjected” (Westermarck 2014, p. 151). In sum, Westermarck proposed that early co-residence played a functional role, causing siblings – or more precisely, any children reared in sibling-like conditions – to not experience sexual desire for one another in adulthood and that this phenomenon was the result of natural selection against the detrimental reproductive effects of inbreeding.

Westermarck’s idea was received with great and immediate interest among his contemporary scholars. The famous anthropologist Sir Edward Burnett Tylor wrote a letter to Westermarck saying that “I should not be surprised to find [your explanation] or something like it the real solution.” Wallace noted the “ingenious and philosophical explanation of the repugnance to marriage between near relatives,” and wrote Westermarck saying “I think you have solved the problem” (Wolf 2014).

Only a few decades later, a number of scholars, among these, most famously Sigmund Freud, furiously criticized Westermarck’s explanation, without ever empirically testing its validity. Westermarck’s critics argued that the moral rules prohibiting incest were themselves evidence against his proposition of an innate aversion. Instead, they claimed that the origins of incest taboos exist because humans have incestuous urges that need to be repressed by moral rules (e.g., Wolf 2014). Although he defended his position with ingenious arguments, the result was that Westermarck’s theory about the natural origins of the human incest aversion lost popularity. But also Freud’s influence in psychology waned over time, and a renewed interest in the so-called Westermarck effect came to be an integral part during the rise of sociobiology in the 1960s and the rise of evolutionary psychology in the 1980s. Only now, eight decades after Westermarck had presented his idea, was evidence gathered to test whether Westermarck was right or wrong.

Empirical Tests of the Westermarck Effect

Anthropological data have been used to test the effects of early co-residence on later attraction. In nineteenth-century Taiwan, young girls were often adopted into a new family and raised together with the family's son, who would become their future husband. Comparing the outcomes of these marriages to other arranged marriages in a series of ground-breaking studies, Arthur Wolf found that in marriages between individuals with co-residence during childhood the fertility rates were decreased and divorce rates were increased. After controlling for several factors, such as health differences between the adopted and nonadopted brides, he concluded that only the spouses' shared childhood residence could explain this difference. In Israeli *kibbutzim*, unrelated children of the community are raised together. Studying individuals raised in this context, it has been found that marriages and romantic relationships are uncommon between individuals who have been raised in the same peer group (e.g., Talmon 1964), also indicating that co-residence in childhood decreases attraction between unrelated individuals. Similar findings have also been presented in studies on *bint'amm* marriages in Lebanon and Morocco.

More recently, Bevc and Silverman (1993) investigated how early co-residence between siblings influenced the probability of incestuous behavior. Here, individuals reporting incestuous behavior were compared to a control group. Incestuous behavior between two siblings, including vaginal intercourse, was associated with decreased early childhood co-residence. In a follow-up study, the same research group categorized a sample of siblings into three groups based on incestuous sexual behavior during adolescence: One group included siblings reporting attempted or completed incestuous genital intercourse; the second group included siblings reporting other incestuous sexual activities; and the third group included siblings reporting no incestuous sexual activities. The results from this study were coherent with earlier results. About 30% of the siblings reporting attempted or

completed genital intercourse had been raised separately for more than a year, whereas the rate of co-residence was much higher in the two other groups.

More indirectly, studies also suggest that individuals growing up with a opposite-sex sibling reacts with more aversion to descriptions of third-party incest (e.g., Lieberman et al. 2003), and that incest between siblings who have co-resided during childhood is perceived as more disgusting than incest between siblings who have not lived together during childhood (Antfolk et al. 2012). In addition to research employing anthropological data and self-report methods, De Smet et al. (2014) studied females' psychophysiological responses to imaginary sexual activity with either their brother or partner and found a stronger disgust reaction associated with the duration of living in close proximity to their brothers, further providing supporting of an Westermarck effect.

Taken together, the results of these studies indicate that co-residence in childhood is indeed associated with decreased sexual interest between two individuals in adulthood. It should also be noted that although the Westermarck effect has received a great deal of empirical supports, it seems clear that co-residence during childhood does not fully explain the why's and how's of human inbreeding avoidance. It is unclear whether it can account for the socio-normative incest taboo Westermarck initially wanted to explain, that it does not seem to explain incest avoidance between parents and their children, and that it is only part of the explanation for incest avoidance between siblings. Moreover, the Westermarck effect is not specifically regulating incest aversion.

Other Kin-Recognition Cues and the Proximate Regulation of Incest Aversion

The Westermarck effect is usually taken to describe a specific mechanism responsible for the general lack of sexual interest between close kin, but co-residence in childhood seems, more generally, to be a kin-recognition cue among

others regulating also other types of social behavior, such as altruistic investment in siblings. While co-residence has been shown to function as a reliable kin-recognition cue, Lieberman et al. (2007) found that its effect is moderated by birth order. In fact, co-residence was associated with altruistic dispositions and incest aversion only when considering behavior towards an older sibling. Older siblings, who can see their own mother gestating and caring for a younger individual, can use this presumably more valid kin-identification cue when considering behavior towards a younger sibling (Lieberman et al. 2007). More recently, a study by Lieberman and Billingsley (2016) showed that the effects of co-residence might in fact be due to the effects of shared parental investment. As biological parents are more likely to use resources on genetically related children than other children, witnessing one's own parents investing in another child might serve as a primal cue, being tightly correlated with co-residence.

Conclusion

Quite irrespective of the extent to which Westermarck was right or wrong, the Westermarck effect is likely one of the well-known examples of evolutionary reasoning in psychology. For this reason, Westermarck himself continues to be a central figure in the history of evolutionary psychology. The vast literature on kin identification is greatly indebted to Westermarck's early proposition, stating that co-residence in childhood decreases sexual interest between individuals in adulthood.

[Inbreeding avoidance](#); [Incest avoidance](#); [Negative sexual imprinting](#); [Westermarck's hypothesis](#)

Definition

A hypothetical psychological effect through which sexual attraction becomes less between people who live in close domestic proximity during the first few years of their lives.

Introduction

Widely applied by evolutionary researchers to the explanation for human incest avoidance, Westermarck effect hypothesized that human tend to develop a strong sexual aversion to those they live closely with during infancy and early childhood. This hypothesis was first proposed by Finnish anthropologist Edvard Westermarck in his book *The History of Human Marriage* (1891), described as a mechanism of inbreeding avoidance.

Westermarck effect is also called negative sexual imprinting, in contrast to positive sexual imprinting. Quite a few evidences have shown the rationality of the Westermarck effect.

The Evolutionary Function of Inbreeding Avoidance

It was hypothesized by Westermarck that humans spontaneously developed a sexual aversion toward individuals they have lived together during childhood (Westermarck 1891, 1934). The hypothesis proposed that inbreeding avoidance might be the result of an evolutionary mechanism instead of a kind of social rule. As concluded by biological perspective, inbreeding can lead to inbreeding depression, which reduces the biological fitness in a given population. Reduced offspring number, lowered growth rate, and corrupted immunity are found related to inbreeding, both in animals and humans (e.g., Keller and Waller 2002). Therefore, an instinctual mechanism to avoid inbreeding is necessary in the process of evolution. Evidence from animals such as female pilot whales (Amos et al. 1993) showed a tendency that individuals would avoid mating with those raised in the same peer or family group, which empirically supported the Westermarck effect or the existence of negative sexual imprinting.

Evidence for Westermarck Effect in Humans

Anthropological and ethnographic studies have paid much attention to Westermarck effect in different cultures and places. One of the best known examples is the Israeli kibbutz system (collective farms), in which children were reared communally in peer groups. Shepherd (1971) found that out of 3000 marriages occurred across the kibbutz system, only 14 were between children from the same peer group. Of those 14, none had been reared together during the first 6 years of life, indicating the possible critical period of Westermarck effect.

Another series of studies focused on the Chinese shim-pua marriage, a tradition of arranged marriage. Shim-pua marriage was a kind of marriage in which a family would adopt a preadolescent daughter as a future bride for their preadolescent son in some areas in premodern China, and the future husbands and wives would be raised together. Research showed that shim-pua marriage were more likely to result in higher rates of divorce and lower fertility rates (Wolf 1995), supporting the hypothesis that individuals who had a history of early childhood experience together may be averse to marriage as adults.

Recent studies tend to examine the Westermarck effect by survey research or in laboratory settings. Data collected by survey showed that separation for at least 1 year during childhood may increase incestuous behavior between siblings (Bevc and Silman 2000). By testing participants' attitude toward sibling incest rather than asking their own experience, research showed that childhood co-residence with an opposite-sex individual predicted the strength of moral sentiments regarding sibling incest (e.g., Lieberman et al. 2003). In an experimental study, participants rated their preference for morphed faces, and results suggested that female participants rated morphed faces that resemble their opposite-sex siblings significantly lower than average faces. However, male participants showed an opposite pattern that similarity to sibling increased perceived attractiveness (Marcinkowska et al. 2013). Psychophysiological techniques were used to test participants' aversion to imagination of sibling incest in a recent study. Results showed

that indicators such as duration of co-residence with a brother of female participants predicted activity of facial muscles related to a disgust expression (De Smet et al. 2014).

Nevertheless, the existing empirical results thought to be supportive evidence for Westermarck effect also have some limitations. For example, in interviews when asking participants the experience about sibling relationship and sibling incest, participants might try to please the interviewer by exaggerating or narrowing down some details, especially when it comes to sexual issues. Similarly, such limitation can be found in self-report survey researches as well. Furthermore, having incest experience does not equal to not being aversive to incestuous behavior. Other factors may also lead to sibling incest. Thus, childhood association between opposite-sex siblings may not be the only predictor of incestuous behavior. Another aspect that has received little attention is the interaction between positive imprinting and negative imprinting (Westermarck effect), both of which seem to influence the mate preference of animals and humans (Rantala and Marcinkowska 2011).

Conclusion

Altogether, over the past century, ethological, anthropological, and psychological approaches have made great attempts to examine Westermarck's hypothesis of the mechanism of incest avoidance, which can be also described as negative sexual imprinting mainly on siblings. Although some of the results received much critics, which put doubt on the methodology of research or the generalization of the findings, the existing studies still contain great value and may give insights to the research field of both sexual imprinting and Westermarck effect.

The part of Europe that loosely includes modern-day France, Germany, Spain, Portugal, and Italy.

Introduction

The first time we see evidence of anatomically modern humans at all is in Africa, about 200,000 years ago. It is a well-respected idea that after they emerged as *Homo sapiens*, or anatomically modern humans, they began migrating up toward Asia, Europe, and the Middle East, likely between 60,000 and 40,000 years ago. However, it is still unclear or whether or not it happened all at once or when the migration may have ended (Eriksson et al. 2012; Hublin 2012; Stringer 2000). Patterns of tool dispersal across Europe and the differences between these tools suggest that there were at least two different migrations of humans into Europe, both with slightly differing characteristics when it came to their material cultures (Hoffecker 2009; Mellars 2006).

In an effort to understand the environment into which modern humans were moving, we can paint the picture of Western Europe during the Marine Isotope Stage 3 (MIS 3, about 60,000–40,000 years ago) as different from what we see today in a variety of ways. MIS 3 was a period of climatic change in Europe between about 60,000 and 30,000 years ago. The environmental changes of the period were characterized

by harsh cold, and large variation in climate, making it difficult for large mammals to adapt, even for fauna that were already considerably “cold-adapted.” Indeed, increases in snowfall would have increased the aridity of the area overall (Bocquet-Appel and Demars 2000). Research illustrating decreases and extinction in other faunal populations helps support evidence that indicates that the environment would have been severely impoverished and likely hard to survive in (Stewart 2007); however, we know that humans do so for several thousand years.

This essay looks more specifically at the migration of humans into Western Europe, examining paths they may have taken, evidence for their presence in sites between Africa and Europe, and hypothesizing what they may have done once they were there (Nigst et al. 2014).

Migration Patterns

According to Bocquet-Appel and Demars (2000), the first appearance of modern humans occurs between 40,000 and 37,000 years ago, around Danube River. By 35,000 years ago, settlements appear all over Eastern Europe and, for the next 2000 years or so, start to creep westward. All of Europe appears to be colonized by modern humans by at least 27,000 years ago (Bocquet-Appel and Demars 2000). The authors note that this final piece of colonization, which appeared in the Iberian Peninsula, was much slower than colonization up until that point. They hypothesize that this could have been due to the presence of Neanderthals, or the harsh environmental circumstances just north of the peninsula. It is possible that humans migrated upward via the Great North European Plain (Bocquet-Appel and Demars 2000).

Evidence for Human Populations

There are three types of technologies characteristic of the era when modern humans were populating Europe. The Aurignacian describes a period of

cultural artifacts that are dated to be between 50,000 and 30,000 years ago, appearing mainly in Eurasia. These artifacts help illustrate the culture of the hominins that produced them, as well as shed light on their cognitive development, especially since the tools from this period are frequently compared with earlier periods of tool development. Aurignacian tools are very specifically associated with modern humans (Nigst et al. 2014; Hublin 2012).

Additionally, a period known as the Protoaurignacian includes small blades and projectiles that are characteristically different from the Aurignacian in the style through which they are made. There is sometimes controversy around when the Protoaurignacian period occurred with respect to the Aurignacian; however some researchers have argued that they may have overlapped and simply indicate different technologies that modern humans produced after they split and took different paths into Europe, with the Protoaurignacian occurring along the southern route and the Aurignacian occurring along the one more Northern (Nigst et al. 2014; Hublin 2012).

Finally, the Bohunician period is one characterized by tools that have been found in areas like Bulgaria and the Czech Republic. The tools here are considered similar to levallois technology (an earlier style of toolmaking for hominins), usually featuring a blade for cutting or scraping. Like most tools, there is a “core” of rock off of which pieces are flaked to create the necessary implement. These tools are usually made of flint (Hoffecker 2009; Richter et al. 2010).

One difficulty is that human remains from the time when they likely colonized Europe are rare. We frequently can only use the remains technologies to represent areas where these first nomadic humans lived, since we can date their creation to the approximate time when humans migrated (Nigst et al. 2008). Fossil remains of Aurignacian tools and artifacts can help map where and how modern human populations migrated. By tracing sites across Europe, we can get an idea of the paths that humans took out of Africa and where they may have settled along the way. Aurignacian artifacts are especially useful because they are so closely associated with modern human behavior

(Nigst et al. 2008). Their remains show us paths that move around the Eastern coast of the Mediterranean Sea, and then diverge slightly, with one moving in to Europe further north of the other; however both do move in to Western Europe between about 36,000 and 40,000 years ago (Mellars 2000).

The similarities between artifacts found at the sites that trace these paths indicate that these technologies originated at the earlier sites along the paths and were transferred geographically as the human troops migrated (Mellars 2000). However, there does appear to be some discrepancies between the technologies found at sites along each path after they diverged, suggesting that it wasn't until after these paths diverged that each group developed the unique technologies they then left behind to be found thousands of years later. It is also possible that a second wave of anatomically modern humans occurred around 45,000 years ago and could have been responsible for the slight variation in technologies seen at some sites (Hoffecker 2009; Mellars 2006).

Researchers will usually date objects by testing levels of radioactive isotopes in carbon-14, a material found in organic objects, while this method has its flaws, recent technological advancements have worked to make it more precise (Hublin 2012).

Evidence from the site known as Willendorf II, in Danube valley region of Austria, features evidence that can provide a stopping point for humans during their migration. A series of blades that were found exhibit two different tool-making procedures, both of which are very highly associated with the Aurignacian period and some associated with the Bohunician (Hoffecker 2009). Both involve removing chips of stone off a central “core,” in such a way as to produce an edge that can be used for scraping or cutting materials. Other tools and artifacts found have been analyzed and compared and are very likely to be from this period as well, supporting the idea that there was a modern human settlement here (Nigst et al. 2014).

The authors discussed the findings and how they related to the whole picture of human migration into Europe. The evidence suggests that there

was a human presence in central Europe around 43,000 years ago. Faunal remains that have been analyzed suggest that the environment at this time was likely a cold steppe environment. However, the presence of trees and the proximity to Danube River would have likely created a varied area, somewhat ideal for settling. It is important to remember that these modern humans will likely have come from an environment much warmer than the ones in Europe, meaning that they would have needed to quickly adapt to the colder temperatures through things like increased clothing, in order to survive (Nigst et al. 2014).

Another dating method takes advantage of a large volcanic eruption which was said to have occurred around 39,300 years ago, in Italy. The resulting ash deposits from this seismic event are relatively easy to trace and allow archaeologists to more accurately date objects (Hoffecker 2009; Hublin 2012). Aurignacian artifacts have been found that clearly originate before this eruption, indicating that there were likely modern humans in Europe prior to this time.

Some of the earliest human sites in Bulgaria, the Czech Republic, and Poland include various tools from the Bohunician period, as well as some human remains dated to about 48,000 years ago. Tools included blades, human ornamentation, and modified blades. While there is little evidence of Bohunician technology in Western Europe, artifacts found in Spain and Italy are dated to come from a similar period between 44,000 and 42,000 years ago; however these artifacts tend to fall into the category of Protoaurignacian. Evidence has also been found for Aurignacian remains in parts of Germany (Hoffecker 2009). It is supposed that the dispersal of these sites and artifacts is representative of movement in a south-westerly direction toward the Iberian Peninsula (Banks et al. 2008).

As rare as it is, parts of a fully modern human skeleton were found in what is now Lebanon, hypothesized to be from around 47,000 years ago. Additionally, findings of beads, tools, and bone artifacts in areas like Turkey, Bulgaria, and Moravia, in the Czech Republic, suggest that there may have been human populations in Europe as early as 50,000 years ago. This may be a better

representation of human colonization, especially since this likely happened in small groups, creating isolated human populations scattered across Europe (Hublin 2012).

Modern Human Interactions in Europe

Bocquet-Appel and Demars (2000) also point out that coexistence between Neanderthals and modern humans can be hard to determine because it would have to be established that both populations were living in the same place at the same time, which can be difficult to pinpoint. Additionally, even once this has been established, it can be difficult to examine the degree to which the two populations would have interacted. While we do have evidence that they did interbreed at some point after modern humans came to Europe (Hoffecker 2009; Stewart 2015), there is still a lot we don't know yet.

Despite this, there is evidence that suggests that as the modern humans moved into Western Europe, they "followed" Neanderthal populations that were moving further south into areas like the Iberian Peninsula, possibly searching for warmer climates (Banks et al. 2008; Mellars 2004). Additionally, more recent evidence does suggest that Neanderthal DNA makes up a fraction of the human genome, especially for those whose origins are in Western Europe (Mellars 1996; Smith 2013). This is very convincing evidence that when modern humans arrived in Western Europe, they were interacting, and breeding, with Neanderthal populations (Stewart 2013).

Evidence of modern human expansion remains in our DNA (Eriksson et al. 2012); however it doesn't appear to be any fossilized remains that can represent an intermediary hominin between humans and Neanderthals in Western Europe, making the understanding of human behavior in Western Europe somewhat more difficult than it is in other areas (Tuttle 1985). We see evidence for Neanderthal genes in our DNA today, so even if we have yet to find this human-Neanderthal hybrid, we do have pretty solid evidence that there was interbreeding (Stewart 2013).

Conclusion

Overall, it appears as though most of the evidence suggests that modern humans were migrating out of Africa between 80,000 and 40,000 years ago and that they were likely not settled in Western Europe until between 30,000 and 40,000 years ago (Mellars 2000; Bocquet-Appel and Demars 2000). The colonized areas of Western Europe appear to be a bit scattered; however by around 33,000 years ago, the populations have grown and are connected enough to be considered a full population area (Bocquet-Appel and Demars 2000). And by around 30,000 years ago, *Homo sapiens* had conquered all of Europe and were its sole inhabitants, for the most part.

It is considered a great feat that the modern human populations were able to colonize Europe despite having evolved in a completely different environment, suggesting that they possessed other skills that allowed them to adapt to the harsh cold of Western Europe. The population size of these human groups as they moved in to Europe was likely relatively small; however it is possible that they had the distinct capability to colonize. There is vast evidence to suggest that modern human populations were producing advanced technologies while still in Africa (Mellars 2000). Their heightened cognitive abilities associated with symbolic thinking, through body adornments, language, and certain technologies, may have made it easy for them to conquer foreign lands (Hoffecker 2009).

Wet-Nursing

Natalie Rosen

University of Pennsylvania, Philadelphia, PA,
USA

Definition

The suckling of another woman's child.

Introduction

Wet-nursing is an ancient, cultural practice in which infants are breastfed by women other than their mother. Among its multitude of social, economic, biological, and religious benefits, wet-nursing has three, primary evolutionary significances: optimization of lactational beneficiaries, logical resource provisioning, and increased community altruism.

History of Wet-Nursing

Wet-nursing dates back to 3000 BC. Occurring first in Ancient Egypt, wet-nursing was seen as the only alternative to a mother's inability to lactate. Without human milk, and with no known human milk substitutes, an ancient Egyptian child was destined for death. Wet-nurses were therefore perceived as saviors. Years later, in Ancient Rome, wet-nurses were often used to nurse unwanted children that had been thrown onto heaps of rubbish. Others utilized the services of wet-nurses to inexpensively nurse the children of slaves in order to cheaply propagate one's supply of labor (Fildes 1988).

The voluntary use of wet-nurses was first protested in the Middle Ages. At that time, "society regarded childhood as a special time of fragility" (Stevens et al. 2009). Newborns were perceived as vulnerable to the "magical properties" of breast milk that differed from their mother's. The notion that "breast milk could transmit both physical and psychological characteristics of a wet nurse"

(Stevens et al. 2009) scared parents into thinking that wet-nursed children would imbibe qualities of the lower class. As a result, the hiring of wet-nurses declined.

Despite the multitude of objections, wet-nursing remained a popular industry during the Renaissance period. Considered a highly organized and well-paid profession, wet-nursing was a source of income for many poor women. Women of the lower classes often became pregnant, got rid of their child, and then sought employment as a wet-nurse. Employment as a wet-nurse had two benefits: a reliable source of income and a means of contraception (lactation prevents ovulation). Poor women of the time were able to feed their families while, simultaneously, ensuring that their familial costs (e.g., the addition of a child) would not grow. With so much popularity, wet-nursing became highly regulated by governmental organizations (Stevens et al. 2009).

The aristocracy dictated breastfeeding practices during the sixteenth and seventeenth centuries. Women of the upper class refused to breastfeed for fear that it was unfashionable and would ruin their figures. Such social pressures prompted the majority of aristocratic women to hire wet-nurses. In fact, French governmental records indicate that, in 1780, only 1000 of 21,000 babies were nursed by their mother (Hrdy 1995).

In the eighteenth and nineteenth centuries, wet-nursing was utilized by members of lower classes more so than upper classes. Increased costs of living and lowered wages during the Industrial Revolution prompted many women to seek additional sources of revenue. Wet-nursing became such a source. Wet-nurses enabled two women to be employed at the same time: one woman was employed by a mother and a mother was employed in a factory setting. Wet-nursing at the time also functioned as a way of lowering infant mortality rates as wet-nursed infants were shipped out of urban metropolises, sites of squalor and disease, to rural peasants.

Although wet-nursing continued to exist at the end of the eighteenth century, through the nineteenth century, and even today, its popularity has diminished. A 1779 work, entitled *Domestic*

Medicine, “displayed an open distrust of wet nurses and their use of home remedies” (Stevens et al. 2009) and advised many women to, once again, breastfeed their own children. Attention was drawn to a wet-nurse’s use of opiates, as a means of quieting children, in the eighteenth century and further prompted the usage of wet-nurses to decline. The incidence of wet-nursing reached its lowest point in the nineteenth century, when artificial feeding became a feasible substitute for breastfeeding. With advances in bottle-feeding and the availability of nutritious and infant-friendly animal milk, the use of wet-nurses continued to decline. By 1900, with the exception of few cultures, the wet-nursing profession was nearly extinct (Stevens et al. 2009).

Optimization of Lactational Beneficiaries

The wet-nursing process may optimize the biological benefits of breastfeeding for both the feeder and infant. Mothers who either lost or discarded their children prior to weaning are able to elicit the same lactational benefits from feeding another child. Furthermore, children who have either lost their mothers before weaning or have mothers unable or unwilling to lactate are still able to gain the nutritional and immunological properties of breast milk. By optimizing the number of lactational beneficiaries, wet-nursing may be viewed as a cultural strategy with significant evolutionary advantages.

Benefits for the Child

Due to the advent of bipedalism, a 4.2 million year-old evolutionary adaptation that narrowed the hominin birth canal, the majority of neonatal neurological development occurs postpartum in order to prevent obstructed labor and reduce maternal mortality. As a result, at birth, the human infant is only born with 25% of its cranial development. Long-chain polyunsaturated fatty acids (LCPFAs), primarily docosahexaenoic acid and arachidonic acid, present in human milk,

correct such cognitive deficits and enable an incremental increase in cognitive development that is proportional to nursing duration. In addition to aiding the development of neurological functions, breastfeeding has been shown to decrease an infant’s risk of type 2 diabetes, obesity, coronary artery disease, gastrointestinal diseases, upper respiratory illnesses, and atherosclerosis (Orlando 1995).

Breast milk also acts to strengthen an infant’s poorly developed immune system. In order to gain immunity from their pathogenic surroundings, infants utilize colostrum, a maternal, mammary gland excretion that is rich in immune factors (Orlando 1995). Unlike bovine milk and milk substitutes, colostrum transfers maternal immunity to environmental-specific pathogens to the infant. Breastfed babies are rich in secretory IgA, IgG, lactoferrin, lactoperoxidase, and lysozymes, compared to their bottle-fed counterparts, and thus have stronger immune systems and lesser mortality rates (Trevathan 2010).

Breastfeeding offers more to the infant than just nutritional and immunological benefits. Cholecystokinin, a hormone, is found in breast milk and acts as a sleep inducer upon consumption. Some argue that breast milk lowers an infant’s levels of bilirubin, a waste product of red blood cell destruction, and thus lowers the probability of newborn jaundice (Stuart-Macadam and Dettwyler 1995).

Benefits for the Breastfeeding Woman

During suckling, oxytocin is released into the bloodstream of the feeder. This repeated release of oxytocin and associated endorphins promote mother-infant attachment, lower blood pressure, decrease cortisol levels, increase withdrawal latency, and increase release of vagally controlled gastrointestinal hormones. Together, these actions cause antistress effects in the feeder (Uvnäs-Moberg 1998).

Breastfeeding may also decrease a feeder’s risk of breast, endometrial, and ovarian cancers (Ma et al. 2006; Heinig 2001). It, too, may reduce the frequency of heart attacks in the feeder.

Prolonged lactation is associated with a decreased prevalence of type 2 diabetes. Further research has suggested that breastfeeding may reduce the severity of anemia, bladder and other infections, and spinal and hip fracture after menopause (Labbok 2001).

Logical Resource Provisioning

Wet-nursing may also be understood as a means of increasing the proportion of economically prosperous individuals in a society and, from another standpoint, the number of individuals capable of receiving successful parental investment. History has indicated that the majority of wet-nurses was employed by financially stable families and, were, themselves, from financially unstable families. When such wealthy mothers delegated breastfeeding responsibilities to poorer women, they effectively altered the fecundity of the population. By paying another woman to breastfeed her child, a mother did not experience the ovulatory-suppressing consequences of lactation and could thus have more children in shorter birth intervals. The wet-nurse, on the other hand, inhibited her ovulatory hormones and thus could not give birth. The high demand of wet-nurses forced many women to constantly feed and thereby extend the duration of their reproductive inability (Hrdy 1999). Since wealthy women hired wet-nurses, wealthy women were able to contribute more offspring to the population than were poorer women. In addition, since such women possessed financial, medical, and agricultural resources, scarce commodities at the time, their many sires received high levels of parental investment and had a lesser probability of early morbidity and disease. In such a sense, wet-nursing ensured that those capable of investing in their offspring were able to reproduce at a greater and more successful rate. In a highly socioeconomically stratified era, wet-nursing, theoretically, guaranteed that resources were provisioned in a logical manner: those with the most resources had the most offspring whereas those with the fewest resources were able to conserve their wealth and distribute it to fewer offspring.

This notion proves that wet-nursing had evolutionary advantages.

Increased Community Altruism

Wet-nursing establishes the notion of milk kin and thereby affects resource provisioning within a community. According to Hamilton's rule, resources are altruistically distributed using the formula, $C < Br$, where "C" equals the cost to the helper, "B" equals the benefit to the helped, and "r" indicates the degree of relatedness between both parties. An individual should be evolutionarily inclined to help someone if the imposed cost is less than the product of the benefits and degree of relatedness (Hrdy 1999). In a community that respects and declares milk kin, or relatedness among all sucklers of the same nurse, all citizens should have higher "r" values between one another than biology would dictate. By increasing the degree of relatedness between community members, wet-nursing should increase altruism and resource sharing within a community.

The notion of milk kin and its effects on community altruism have been illustrated throughout history. Islamic law specifies three types of kinship: relation by blood (*nasab*), affinity (*musahara*), and milk (*rida'a*). The latter form, *rida'a*, is denoted by the "relationship between a child and a woman, not its own mother, who nursed it" (Altorki 1980) and may be used to determine marriage suitors and potential allies. Muslim law prohibits marriage between *rida'a* relatives just as it does between *nasab* relatives. If a child was breastfed by a woman different from his mother, he forged new kinships and lost potential marriage options (Gil'adi 1999).

While *rida'a* relationships may bar marriage options, they, too, must be thought of, in the context of Islamic history, as a means of extending familial ties. As seen in Hadith literature, wet-nursing was initially practiced by an Islamic community in order to broaden the network of relatives on whom one could rely for assistance and support. By forcing Muslims to marry outside of their residential boundaries, wet-nursing enabled

individuals to meet new people from diverse, surrounding communities. Muslim believers were encouraged to seek partners beyond the boundaries of their own patrilineal-patrilocal extended families in order to inspire a shared world view on common aims (Gil'adi 1999). Forcing exogamous marriages, *rida'a* ties created relations between sedentary Islamic communities, such as Mecca, and the tribes of the desert. As Islamic women continued to nurse children of other faiths in surrounding communities, the number of Islamic followers skyrocketed. By decreasing one's marital options, wet-nursing served to expand the Islamic contingency (Gil'adi 1999, p. 120).

By broadening one's array of diverse relatives, wet-nursing also functioned as a means of establishing familial and/or national alliances. According to Jane Khatib-Chahidi, "it is reported that when Masai of East Africa wanted to make a lasting peace with an enemy tribe, the respective tribes would bring a cow with a calf and a woman with a baby. The two cows would be exchanged and the enemy's child suckled at the breast of the Masai woman; the Masai baby would be suckled by the woman from the enemy tribe" (Maher 1992). To strengthen relations with surrounding clans, the Hindus of India, specifically the royal Rajputs, chose their children's wet-nurse from a nearby, pastoral tribe.

While wet-nursing established alliances between neighboring, often conflicting, communities, it was also used to strengthen intra-group unity. In the Ashimadek clans of Chitral in the Hindu Kush, every infant was breastfed by every mother in the clan (Maher 1992). With the constant exchange of infants, milk-relationships were consistently formed. Familial relations were broadened and individual's expanded their resources and sources of comfort. Additionally, such an exchange of infants between neighbors yielded assurances that neighboring families would not cheat on one another. Preventing options of adultery, wet-nursing in turn strengthened families and inspired trust.

Wet-nursing also served to bridge government officials with their constituents. Akbar, the Mogul Emperor of Delhi and descendant of Genghis Khan, would punish milk kin with less severity, regardless of their crime. In fact, during one court

hearing, he stated: "between me and Aziz is a river of milk which I cannot cross" (Maher 1992). In essence, wet-nursing functioned as a transaction: suckling of an infant was exchanged for lifetime loyalty.

Overall, the altruistic consequences of wet-nursing prove that culturally determined "r" values are important in determining a species' evolutionary tendencies. However, additional research should be conducted to determine the extent to which culturally and biologically determined "r" values are related.

Conclusion

Clearly the milk-relationship is highly complex. In addition to providing biological benefits to both the nurse and nursling, wet-nursing has functioned as a social, economic, and political force throughout history. Although in decline after the introduction of artificial and bottle-feeding methods, wet-nursing remains a religious practice in many parts of the world. Constructing kinships, spreading religion, forming alliances, and enabling economic mobility, wet-nursing is not simply a biological phenomenon. Rather, its complex, biocultural roles are intertwined with its deep evolutionary history and significance. As more than just a viable alternative to maternal lactation, wet-nursing yields an optimization of lactational beneficiaries, logical resource provisioning, and increased community altruism. With such advantages, the cultural practice of wet-nursing may be seen as an evolutionarily advantageous strategy.

What Makes a Tool

Madhur Mangalam
Department of Psychology, University of
Georgia, Athens, GA, USA

Definition

A tool is an object that extends the action capability of the user by transforming the body into a body-plus-tool system, such that the biomechanical fit of the body of the user, the object, and the goal(s) of the user collectively channel the organization of movements in action.

Introduction

All our technology relies on skillful tool use; how we manufacture and use tools is perhaps what distinguishes us from other animal species more than anything else. Archeological remains indicate that we have been using tools for at least 3.3 million years (Harmand et al. 2015). Tool use is considered to have been a key driver of our evolution; independent pieces of research have revealed close associations among tools, language, and cognition (Ambrose 2001; Gibson and Ingold 1993).

Tools are not unique to humans; nonhuman animals use tools as well. Chimpanzees, *Pan troglodytes* (Boesch et al. 2009; Sanz and Morgan 2007), and capuchin monkeys, *Sapajus* spp. (Mannu and Ottoni 2009), use sticks to fish for termites from their nests and honey from beehives, and New Caledonian crows, *Corvus moneduloides*, use stick tools to extract wood-boring beetle larvae from crevices in branches (Hunt 1996). Wild bearded capuchin monkeys, *Sapajus libidinosus* (Fragaszy et al. 2004; Mangalam and Frigaszy 2015; Mangalam et al. 2016), and chimpanzees (Boesch and Boesch 1981; Hannah and McGrew 1987) use anvil-and-hammer tools to crack open palm nuts and other encased food. Bottlenose dolphins, *Tursiops truncatus* (Smolker et al. 1997), and humpback dolphins, *Sousa chinensis* (Parra 2007), hold basket sponges over their rostrum, presumably to protect it while rummaging along the sandy floor of the sea. Stimulated by the apparent ubiquity of tool use in the animal kingdom, researchers have been relentlessly addressing questions about the continuity and discontinuity in tool use among humans and non-human animals.

Tools are relevant to many areas of scientific enquiry. Neurophysiological studies on people with apraxia – who lose their ability to conceptualize, plan, and execute actions, especially with familiar handheld tools (e.g., a rake) – regularly discuss tools (see, e.g., Goldenberg and Hagmann (1998)). Ergonomics is another area where discussions about tools are prevalent, frequently about comfort or discomfort (Kuijt-Evers et al. 2005) and occasionally about movement

disorders following prolonged use (Pilgian et al. 2000). Studies on humans involve everyday handheld tools, and nobody debates that these objects are “tools.” However, the challenge arises when comparing behavior involving an object across species, as then one needs to have an idea of when an object is a tool.

What Makes a Tool?

While both lay people and researchers can intuitively and unequivocally identify a tool, as of now, there is no consensus in the scientific literature on what makes a tool. The same object can be used as a tool and as a non-tool, thereby questioning when exactly in time and space does an object become a tool. In light of these uncertainties, ideas about tool use began with the descriptions of the form of an object and the functionality of behavior but have recently graduated to account for the developmental origins of tool use.

Definitions of Tool Use

Epistemological discussions on tools are most common in the physical anthropology and ethology literature. Typically, these discussions revolve around what constitutes tool use and not what makes a tool per se. Nonetheless, these have led to the development of a few ideas on tool use which have been instrumental in guiding research on tool use in nonhuman animal species for the last four decades:

the manipulation of an inanimate object, not internally manufactured, with the effect of improving the animal's efficiency in altering the position or form of some separate object.

– Alcock (1972), p. 264.

the external employment of an unattached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself when the user holds or carries the tool during or just prior to use and is responsible for the proper and effective orientation of the tool.

– Beck (1980), p. 10.

the external employment of an unattached or manipulable attached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself,

when the user holds and directly manipulates the tool during or prior to use and is responsible for the proper and effective orientation of the tool.

– Shumaker et al. (2011), p. 10.

As researchers became more interested in the varieties of behavior with objects observed in nonhuman animals, more precise definitions of tool use were sought, to determine if a given behavior constituted tool use. Beck's (1980) definition was exceptionally well accepted for more than three decades, until Shumaker et al. (2011) provided a revision along with the rationale for it (italicized in the definition above). Their revision has been the basis for the most updated catalogue of the known cases of tool use in nonhuman animals (Shumaker et al. 2011).

Despite being the most comprehensive definition of tool use in the scientific literature, Shumaker et al.'s (2011) definition is subjective and open to interpretation. Few would disagree that these challenges hold for any definition of tool use because of the observational nature of most studies, especially in nonhuman animal species. However, there are a few other challenges with defining tool use as well.

Challenges with Defining Tool Use

Without exception, the definitions of tool use hold the premise that all behavior involving an object and accomplishing a few given conditions belong to a single class of behavior, “tool use,” and that an object is a “tool.” Consequently, the focus of research in physical anthropology and ethology has mostly been on deducing whether a given behavior constitutes tool use, instead of on examining the actions with an object. This type of distinction between tool use and non-tool use poses a few challenges to our understanding of this behavior:

1. Any attempt of defining tool use overestimates the differences between tool use and non-tool use and underestimates those among tool use, as definitions tend to not account for the actions with an object. A pole used to displace an object and a hammer used to hit a nail are both tools, even though the actions with them differ considerably. A pole used to displace an object is a tool, but a laser pointer (or a pole)

- used to point on a screen is not (why isn't any kind of pointer a tool?) even though the actions with them do not differ considerably.
2. Definitions of tool use demand inferences about the intention of the user. However, when observing a nonhuman animal species using an object, the judgment of the observer may not necessarily coincide with the intention of the user. Thus, studies on tool use in nonhuman animals based on these definitions are highly susceptible to anthropomorphic biases.
 3. These definitions do not stimulate comparisons among cases of tool use, but instead halt discussions once a behavior has been ascertained to constitute tool use.

In the face of these challenges, many researchers have endorsed a perception–action perspective on tool use, which bypasses the distinction between tool use and non-tool use, but instead focuses on the tool-use actions.

A Perception–Action Perspective on Tool Use

Lockman (2000) opposes that tool use entails a gradual process of exploration and discovery that leads to perceptual learning, exploits the relation among an object and a surface in the environment, and encompasses only species-typical movement. The perception–action perspective on tool use has been guiding research on the development of tool use for the last two decades, with the objective of understanding how the organization of tool-use actions emerge from the dynamical interactions among features of the body of the user, the tool, and the goal(s) (see Smitsman and Bongers (2003) for an extended discussion on the fundamentals of the perception–action perspective on tool use and Mangalam and Frigaszy (2016) for discussion with an emphasis on nonhuman animals). So, most investigations comprise longitudinal studies examining spatiotemporal changes in tool-use actions across an extended period, especially during early life.

Cross-sectional studies on the origins of percussive tool use in human infants back the perception–action perspective on tool use. The accuracy and delivery of force improve in 7–14-month-old infants enabling spontaneous actions to become well suited for instrumental hammering

and tool use later (Kahrs et al. 2012), as well as in 12–18–24-month-old toddlers with improving postural stability and increasing motion of the elbow (Fragaszy et al. 2016). The spatiotemporal properties of percussive actions also change with age (19–35 months); older children show more distal control of their actions, and thus a higher accuracy, than younger children (Kahrs et al. 2014).

Longitudinal studies on percussive tool use to crack open palm nuts in wild bearded capuchin monkeys at Fazenda Boa Vista, Piauí, Brazil – the EthoCebus study site (Eshchar et al. 2016) – also back the perception–action perspective on tool use. Initially, when about a year old, juveniles begin to percuss nuts and nutshells against surfaces (combinatory, single-object actions) and against other nuts and nutshells (combinatory, two-object actions). Subsequently, they use pebbles as percussive tools. Eventually, when about 3.5 years old, they begin to use bigger stones, as until then, they cannot lift a heavy stone or produce an adequate force with a light stone because of their small body mass. Prolonged exposure to nut-cracking activity and the remains near anvils facilitate the ontogeny and development of stone tool use in wild bearded capuchin monkeys.

Among the chimpanzees at Bossou, Republic of Guinea, West Africa, the development of the sequence of percussive actions is similar to that in the bearded capuchin monkeys at Fazenda Boa Vista; about 2.5-year-old juveniles have already acquired the actions necessary to begin the nut-cracking activity, but they often take a few years to combine those appropriately (Inoue-Nakamura and Matsuzawa 1997).

These examples illustrate that tool use is not a discontinuous developmental milestone that demands a new level of cognitive resources, but instead the developmental origins of tool use lie in the perception–action routines of a species, especially those in the beginning few years of life when individuals explore their environment. These examples also suggest that the differences between tool use and non-tool use are gradual (i.e., of a degree) and not a fundamental one (i.e., of a type). When exactly in time and space actions constitute tool use is still debatable.

One implication of the perception–action perspective on tool use is that studying the body, the tool, or the goal(s) in isolation might lead to erroneous conclusions, which is especially relevant for comparisons of tool use across individuals, populations, and species.

Thus, the perception–action perspective on tool use has one word answer – actions – to the question: what makes a tool? Whether an object is a tool depends on how it is used (i.e., the actions with it) and not the anatomy of the object (Ingold 1993, 1997). Most recent advancements indicate that it might be more appropriate to consider “tool” as an adverb for describing the actions with an object and not as a noun. This linguistic change in how we think about tools has implications for our understanding of their use.

Conclusions

While both lay people and researchers can intuitively and unequivocally identify a given object as a tool, there is no consensus yet on what makes a tool, and there may never be. However, for the last two decades, researchers have been increasingly acknowledging that the actions with an object, and not the anatomy of an object, make that object a tool. Thus, researchers have been increasingly studying tool-use actions, which may eventually help in bypassing the distinction between tool use and non-tool use. A developmental perspective that focuses on spatiotemporal changes in tool-use actions is proving helpful. A key challenge is to explain how all behaviors involving an object lie on a continuum, without overestimating the differences between tool use and non-tool use and underestimating those among tool use.

Why Humans Are Unique

Jennifer Vonk
Oakland University, Rochester, MI, USA

Synonyms

[Hominids](#); [Special](#); [Unusual](#)

Definition

The ways in which humans are different from other animals and why they have come to be so unusual.

Introduction

A central focus in the study of comparative cognition is the question of what it is that makes humans unique. There is no denying that humans stand apart from the rest of the animal kingdom in several key domains. For instance, no other species has mastered advanced technology or has the capacity to so dramatically alter its environment. No other species has mastered the art of travel using vehicles rather than natural affordances. No other species has travelled off the planet in search of other life forms. These facts are observable and uncontested. However, a much more contested topic in comparative psychology is the extent to which humans are similar or different from other species in terms of their fundamental cognitive capacities, which presumably give rise to such inventions. Although several feats accomplished only by humans have been outlined, it is less clear whether other species share some cognitive capacities that underlie such feats, even if

these capacities do not reach the same upper bounds with which they are expressed in humans.

A recent set of studies were conducted to demonstrate that, although humans alone engage in the cooking of food, our closest living relatives – chimpanzees – might have the requisite capacities to engage in similar acts, even though they have never been observed to do so (Warneken and Rosati 2015). The article generated much discussion in part because the studies did not show that chimpanzees exhibited a causal understanding of how to recreate the transformative properties of the cooking agent. Discussions such as these highlight the common resistance to the notion that humans are unique and the opposing resistance to the notion that humans are qualitatively special when compared to other species, in particular the other apes. These discussions also highlight the need to look beyond observable similarities in the types of behaviors being performed by different species in order to probe the underlying mechanisms giving rise to such behaviors.

Tool Use

Some key cognitive components were identified early on as being exclusive to humans. These included tool use, language, abstraction, imitation, culture, causal reasoning, theory of mind (i.e., the capacity to reason about mental states in others), and other-regarding preferences. Researchers have chipped away at such assertions revealing evidence for tool use in a variety of species including birds, elephants, bears, and non-human primates (for review see Shumaker et al. 2011). However, although it is commonly accepted that some other species may use tools, the manner in which they do so is generally not indicative of a deeper level causal understanding of the tool's properties.

Language

Nonhuman apes have also mastered various components of language – most notably the bonobo, Kanzi (Savage-Rumbaugh et al. 1998). Despite

these impressive accomplishments, researchers generally agree that the language exhibited by nonhuman apes does not approach the complexity or generativity of human language, and non-humans do not express thoughts about the past or future. In humans, language can be used to express abstract ideas about constructs that have no observable referents.

Abstraction

Indeed, it was often argued that language held the key for the emergence of abstract concepts such as similarity and difference at a conceptual level. Language is surely related to the capacity to express thoughts about unobservables, such as causal forces (e.g., gravity, transfer of force) and mental states (e.g., thoughts, beliefs, intentions). As such, it follows that, without human-like language, the ability to reason in the abstract, in particular about unobservables such as mental states, would not emerge. Thus, other animals should not be expected to represent concepts for thoughts, beliefs, and the like. Indeed, theory of mind is one of the most controversial topics in comparative cognition as researchers passionately debate whether there is convincing evidence that any other species are capable of going beyond reasoning about observable cues correlated with underlying mental states in order to infer the underlying mental states themselves. Vonk and Povinelli (2006) hypothesized that the ability to reason about unobservables, which would subsume both causal forces in the physical realm and mental states in the psychological realm, may be the primary capacity distinguishing humans from other animals.

Prosociality

Animals that reason about others' mental states are capable of showing empathy for the plight of another. Researchers have argued that animals do have empathy. In fact, even rats have been shown to release trapped cage-mates and to share desired chocolate with their cage mates once rescued,

suggesting a level of compassion for their compatriots (Ben-Ami Bartal et al. 2011). However, other explanations for the behavior have been provided with less lofty interpretations. Perhaps the rats behaved to reduce their own feelings of distress, for example. One puzzle is why observations of helping or prosocial acts, in the absence of benefits for the actor, are so uncommon if animals do have concern for the well-being of others. In experimental paradigms, little evidence for prosocial sentiments has been observed. Where it does occur it is in limited contexts (see Cronin 2012 for a review) and can often be explained through mechanisms such as reciprocity (e.g., Carter 2014).

Imitation and Culture

Understanding the knowledge states of others has direct consequences for other aspects of uniquely human behavior. Originally, researchers believed that only humans could learn through observation to imitate the actions of others. This notion was dispelled when Subiaul et al. (2004) demonstrated that monkeys could learn the correct sequence of images in a cognitive imitation task. However, although it is now accepted that many animals can learn through observation, including learning the reputations of other individuals, animals do not seem to use these capacities to explicitly teach others the extent of their own knowledge. Thus, while researchers have championed findings of common gestures and tool using techniques across chimpanzee and orangutan "cultures" (Whiten 2011), there is nothing on the level of human pedagogy, including schools, text books, instruction manuals, informational videos, and so on, elsewhere in the animal kingdom. The ability to communicate with language surely facilitates these behaviors as well.

Conclusion

It should be clear then that there is no single ability that differentiates humans from other species. Rather, there is a constellation of related traits all

built upon the foundation of language and abstraction that converge to predict uniquely human traits and behaviors. The question remains as to why humans alone would evolve this particular constellation of traits. Vonk and Aradhye (2015) have suggested that humans are uniquely positioned between predator and prey in an arms race to out-compete each other as well as more physically formidable species in the hunt for prey, which might also benefit from the anticipation of others' intentions and actions. Humans have also formed agricultural societies to support close communities, which requires the ability to communicate and cooperate. Thus, it is likely that humans evolved more complex cognitive capacities in order to create and mine food sources to sustain the growth of human communities in a manner not seen in other species, which rely on different subsistence methods. The flexibility required by humans to exploit so many different food sources has allowed them to prevail in more diverse environments than those encountered by other species, including travel to outer space. This flexibility, necessitated by a generalist and exploitative diet, may have simultaneously necessitated larger brain size, which subsequently supported the advance cognitive traits expressed in humans today.

Definitions

A suite of interrelated other-regarding behaviors that cultivate and regulate complex interactions within social groups, a book written by Marc Bekoff and Jessica Pierce.

Introduction

Wild Justice was written by Marc Bekoff and Jessica Pierce and was published in 2009. In their book, the authors attempt to shed light on what it means for animals to have morality. To do so, they focus on three main key points: cooperation, empathy, and justice. The authors first define nonhuman animal morality as “a suite of interrelated other-regarding behaviors that cultivate and regulate complex interactions within social groups” (p. 7). Through the combination of these traits, Bekoff and Peirce suggest that morality is not unique to humans but is an evolved trait that is shared with other social mammals.

Cooperation

In examining the first key point, cooperation, the authors begin by stating that at first glance, evolution appears to be counterintuitive to Darwinian theory, given that competition to survive and reproduce is what drives evolution. However, as Bekoff and Pierce explain, evolution allows for cooperation, which in turn promotes biodiversity. The authors discuss ultimate explanations of cooperation and how cooperation may have evolved over time. Such explanations include kin selection, reciprocity, mutualism, and the controversial explanation that Bekoff and Pierce support called group selection (i.e., a proposed mechanism of evolution in which natural selection acts at the level of the group, rather than at the individual level). After providing different examples of cooperation, the authors propose that for cooperation to be considered a “moral” behavior, the cooperative behavior must contain a high level of emotional complexity, cognitive complexity,

and flexibility. Hence, the cooperative animal should be capable of complex cooperative behavior and not simpler forms of cooperation.

Empathy

Bekoff and Pierce define empathy as “the ability to perceive and feel the emotion of one another” (p. 87). The authors break this down and expand on it more by arguing that empathy is when one individual is able to share the emotional state of another individual and is a class of behaviors that evolved in complexity over time. It would make sense, then, that empathy is an adaptive trait, as being able to share an emotional state would assist individuals of a social group when avoiding danger and having better social relations with other members in the group. Bekoff and Pierce contend that empathy may facilitate cooperative and altruistic behaviors. The authors then close by citing examples of research examining empathy in a variety of animals, such as rats, whales, dolphins, and elephants, making the case that empathy (in some form) is not unique to humans but has evolved in a variety of social species.

Justice

The authors use the term justice to describe the concepts of fairness and equality in the animal kingdom. They point out that there has been very limited research examining justice, with almost all studies focusing on primates with controversial results. Bekoff and Pierce propose that it may be wise to study social play behavior in other social animals, such as dogs and wolves, to gain a better understanding of justice. They argue that play behavior provides elements such rules, agreement to obey said rules, and consequences for defectors. The authors suggest that studying social play in animals will help researchers gain a better understanding of justice in animals and how it relates to morality. Bekoff and Pierce suggest that in regard to morality, justice is the most complex and evolved set of behaviors that are built upon cooperation and empathy.

Conclusions

The authors conclude the book examining the philosophical aspects of morality. They recap on their definition of morality and argue that it fits into the philosophical framework. They attempt to address limitations and reservations that readers may have about their idea of animal morality. Lastly, they conclude that morality is indeed not unique to humans and is shared with a variety of taxa but that there is still much research in this area to be conducted.

Will After Death

Jacob Peedicayil
Christian Medical College, Vellore, India

Synonyms

[Testament](#)

Definition

A legal document by which a person expresses his or her wish as to how his or her property is to be distributed at death.

As discussed elsewhere in this work (Peedicayil 2018), cultural inheritance involves the storage and transmission of information by communication, imitation, teaching, and learning. In this context, there is evidence that complex social behaviors like human altruism and mate choice (Rushton et al. 1986), social attitudes (Martin et al. 1986), personality (Eaves et al. 1999), and the human sex ratio (Lipatov et al. 2008) are culturally transmitted. The cultural transmission of such behaviors, for obvious

reasons, will occur effectively only in an animal species that is social, i.e., where the members live in groups and interact freely with one another. Human beings are the prototype of that type of animal species and the groups they live in are termed societies (Wilson 2000). Indeed, the famous Greek philosopher Aristotle had stated “Man is by nature a social animal” (Aristotle 2015). All of man’s unique social behavior is pivoted around the use of language (Wilson 2000).

With reference to will after death, it is a phenomenon peculiar to humans due to the advanced level of development of cultural inheritance in comparison to other animal species. Will after death is a legal document by which a person (the testator) expresses his or her wish as to how his or her property is to be distributed at death and names one or more persons (the executor) to manage the estate until its final distribution (Wikipedia 2018). After the demise of the testator, the executor or administrator must locate the will and present it to the local probate court with a certified copy of the testator’s death certificate. Wills have been in existence for thousands of years (Wikipedia 2018).

William Hamilton

Jussi Lehtonen
University of New South Wales, Sydney,
Australia
School of Life and Environmental Sciences,
Faculty of Science, University of Sydney,
Sydney, NSW, Australia

Definition

One of the most influential evolutionary theorists of the twentieth century. Hamilton made fundamental contributions to social evolution theory, the theory of sex allocation, the evolution of senescence, and many other topics.

Introduction

Few evolutionary biologists have achieved the kind of legendary status that William Donald Hamilton holds. His reputation is of course mostly due to his enormously influential body of work and is only further bolstered by his unusual and quirky character which inspired countless stories. Hamilton may not have published a particularly large number of papers by today's bloated standards, but his influence on modern evolutionary theory is almost unrivalled. His major contributions include kin selection theory, sex allocation theory, the modern mathematical approach to studying the evolution of senescence, the evolution of dispersal strategies, and the evolution of sex. Indirectly, or by extending work of other

researchers, Hamilton contributed to evolutionary game theory, the mathematical study of the levels of selection, the study of evolution in age-structured populations, and related methods such as sensitivity analysis. His work was also a major influence on Richard Dawkins' championing of the selfish gene or gene's eye view concept. Hamilton's work remains relevant and influential, if sometimes divisive and controversial, to this day. Here the focus is largely on the lasting impact Hamilton's work has had on evolutionary biology. More detailed information on Hamilton's life can be found in a book-length biography by Ullica Segerstråle (2013), a shorter biographical article by Alan Grafen (2004), and in the three-part volume of Hamilton's collected papers interlaced with (auto)biographical essays (Hamilton 1996, 2001, 2005) from which much of the biographical details here are sourced.

Brief Biography

Though born in Cairo in 1936 to New Zealander parents, William Donald Hamilton grew up in Kent in South East England. It was clear early on that he was fascinated by nature, by plants and their colors, by insects, and by other animals. His interests were encouraged, and he spent much of his time collecting butterflies using a net and killing bottle given to him by his mother. But by way of this hobby, he was also introduced to some of the secrets of his eventual profession: E.B. Ford's book *Butterflies*, a present from his parents, was not just about butterflies, but also contained sections on genetics and on the study of evolution, sparking young Hamilton's interest. He had other, perhaps more mischievous interests too. One was bombs, which after some youthful experimentation resulted in a near-fatal explosion, permanently shortened fingers, and shrapnel in his chest.

Hamilton began his undergraduate education at the University of Cambridge in 1957 and graduated in 1960 with a degree in genetics. After some difficulty in finding a welcoming host institution, Hamilton eventually became a graduate student at the London School of

Economics. He produced his most celebrated work as a graduate student (see the next section), but it would take some time before the importance of this work would be realized.

Although Hamilton would be awarded his PhD only in 1968, he took up a lectureship at Imperial College in London already in 1964. In 1978, he joined the University of Michigan as a professor and eventually returned to England in 1984 after accepting a Royal Society Research Professorship at the University of Oxford, where he would remain for the rest of his life. Hamilton passed away on March 7, 2000, at the age of 63.

Kin Selection and Social Evolution Theory (1963 onward)

If there is a single research theme that Hamilton is best known for, it is no doubt his groundbreaking work on the evolution of social traits and in particular the evolution of altruism. Hamilton produced his most famous articles (Hamilton 1964a, b) as a graduate student (for a personal account, see Hamilton 1996). The publication process turned out to be difficult and slow, so slow in fact that a shorter and less widely known article on the same topic was published in the previous year (Hamilton 1963) despite being written after the more well-known 1964 papers. Perhaps encouragingly for contemporary graduate students struggling to finish their theses, Hamilton was from time to time wracked with doubts about being a fraud and crank, occasionally losing confidence in his ideas, but his perseverance paid off.

What is it, then, that made kin selection so special? Despite partial attempts at explanation (by luminaries such as Charles Darwin, Ronald Fisher, and John Haldane), the evolution of altruism remained poorly understood until Hamilton's insights. The difficulty is that altruism, by definition, increases the fitness of the recipient of altruism, but decreases the fitness of the donor. It is then hard to reconcile this with the fact that natural selection should decrease the frequency of alleles that are associated with low fitness. How can an allele that decreases the carrier's fitness increase in frequency in the population?

Kin selection theory in its modern form is multifaceted and not quick to ingest in its full scope, but Hamilton's central insight was simple. Consider an allele that induces altruistic behavior toward others, carried by an individual organism whom we shall call the donor. The donor will be surrounded by other individuals, some of which may carry a copy of the same allele. Now if the donor can direct its helping behavior toward an individual (whom we shall call the recipient) that is more likely than average to carry such a copy, the help will in fact contribute toward increased success of the helping allele via the recipient. In other words, an allele that can preferentially help copies of itself may be successful and increase in frequency, despite seeming to cause purely altruistic behavior and a fitness detriment to the donor at the phenotypic level. Whether allele frequency does in fact increase depends on the costs to the altruist, the benefit to the recipient, and the probability that the recipient carries a copy of the allele for altruism.

Hamilton famously encapsulated the condition for increase in frequency of the allele in what is now known as Hamilton's rule:

$$rb > c \quad (1)$$

Here, c encapsulates the cost to the altruist, b the benefit to the recipient, and r is relatedness between altruist and recipient. Hamilton realized that, under certain conditions, relatedness r is a measure of the likelihood (relative to the population average) that the recipient carries a copy of the altruism allele. Hamilton's rule is highly intuitive: as long as the benefits scaled by relatedness overcome the cost to self, an altruistic trait can spread in the population. It is important to note that the preferential treatment of closely related individuals need not be a conscious decision, nor does it require active recognition of kin. Any process that leads to interactions between relatives (such as limited dispersal from one's birthplace) can have a similar effect. Kin selection does not require a brain or active choice.

Kin selection and Hamilton's rule have seen various developments over the years. Hamilton's central insights still remain at the core of the

methodology, while others have pushed the field further and developed highly general (e.g., Queller 1992), as well as highly practical and streamlined, kin selection approaches and methods (e.g., Taylor and Frank 1996). Kin selection has also been at the center of heated debates regarding its importance and generality (e.g., the highly critical Nowak et al. 2010, and numerous responses in defense of kin selection that followed), as well as debates between kin selection and alternative approaches to social evolution theory, in particular so-called group selection models. Hamilton himself, however, had a positive outlook on group selection (or multilevel selection) models when properly formulated (Hamilton 1975a), and it can be shown that despite different notations and modeling traditions, the central approaches to social evolution theory are equivalent and ultimately linked by a common set of mathematical components (Lehtonen 2020). Despite controversies and debates, Hamilton's legacy in social evolution theory lives on.

Other Major Scientific Contributions

Although Hamilton is most widely recognized as the father of kin selection, he made several other key contributions to evolutionary theory. This section covers a selection of these contributions, in the order that Hamilton first published on the topics (indicated by the year in brackets after the titles).

Senescence (1966)

Whereas many of Hamilton's papers were inspired by Ronald Fisher (one of Hamilton's scientific role models) and built upon his work, "The moulding of senescence by natural selection" (Hamilton 1966) was a rare exception in that it actually corrected a mistake by Fisher. Fisher wrote "It is probably not without significance in this connexion that the death rate in Man takes a course generally inverse to the curve of reproductive value" (Fisher 1930), suggesting that

reproductive value should be the central factor that drives the evolution of senescence and ageing. Hamilton showed this to be incorrect and instead demonstrated that selection on age-specific mutations on mortality and fertility can be approximated by implicitly differentiating the so-called Euler-Lotka equation, thus finding the derivative of the Malthusian parameter which approximates fitness. It is arguably this mathematical technique that is the most influential aspect of the 1966 article. In addition to its impact on mathematical research on senescence, Hamilton's method has been influential in the general development of the mathematical analysis of evolution in age-structured populations (Charlesworth 1994), and it is perhaps the earliest clear forerunner of sensitivity analysis (Caswell 2019).

Sex Allocation (1967)

In addition to altruism, another question that had stumped Darwin was the evolution of the sex ratio: why are females and males typically born in equal numbers? This problem was famously solved by Düsing (1884) and Fisher (1930), who pointed out a very powerful argument selecting for equal sex ratios. Theoretical progress was slow for some decades, until Hamilton's (1967) analysis of the problem. Hamilton examined various situations where assumptions that Fisher had made do not hold, laying the groundwork for modern research on sex allocation (West 2009). The most enduring contribution of this paper is the theory of sex allocation under local mate competition (LMC): natural selection results in female-biased sex allocation if the population structure is such that brothers compete for matings. Hamilton's sex allocation article was instrumental in the development of arguably one of the most successful areas of evolutionary biology (West 2009). Furthermore, Hamilton's use of an approach he called the unbeatable strategy was influential in the eventual development of evolutionary game theory by John Maynard Smith and George Price (Maynard Smith 1982; Maynard Smith and Price 1973). Hamilton regarded this early paper very highly among his own

publications: “I am more proud of this paper than of almost any other I have written. Perhaps that is most of all because I believe it helped sex-ratio theory well on its way to being the section of evolutionary theory that best proves the power and accuracy of the Neodarwinian paradigm as a whole” (Hamilton 1996).

The Evolution of Gregarious Behavior (1971)

The Hamilton 1971 publication “Geometry for the Selfish Herd” was largely motivated by previous claims that schooling, flocking, and herding behaviors of animals were due to selection at the population or species level. Hamilton shows that there is no need to appeal to selection at higher levels, and the behaviors can be explained by individual-level selection on cover-seeking to reduce one’s own chance of being caught by a predator. The central idea in this paper is often confused with the “dilution effect,” but the concepts are very different. The dilution effect relies on individual-level predation risk being diluted in larger groups even if all individuals are at equal risk, whereas Hamilton’s selfish herding is underpinned by intragroup differences in predation risk (Lehtonen and Jaatinen 2016). Hamilton’s foray into the evolution of herding behavior ended up being one of the most highly cited articles in the *Journal of Theoretical Biology* – Hamilton (1964a) being the most highly cited one.

Dispersal Strategies (1977)

Hamilton’s collaboration with Robert May addresses another question on the evolution of the spatial distribution of organisms, but both the question and resolution are quite different compared to selfish herding. The title of the paper, “Dispersal in stable habitats” (Hamilton and May 1977), already suggests the major novel finding of the article. Previously, it was widely thought that if habitats are stable and dispersal is costly, there is no advantage to be gained by

dispersing from one’s home site. Using a simple model with a striking and surprising outcome, Hamilton and May show this to be far from the truth: even in perfectly stable habitats, and even if migration is so risky that the probability of survival for a migrant approaches zero, it still pays off to commit more than half of the offspring to migration. Although the original model was not framed in a kin selection context, it has a kin selection flavor to it. If reproductive opportunities at the home site are limited, there is little to be gained by competing with close relatives, and it may pay off to disperse and compete with unrelated individuals instead, even if the odds of surviving dispersal are very low. Frank (2013) discusses how extensions of kin selection theory can be used to interpret Hamilton and May’s model explicitly from a kin selection angle and to unify seemingly disparate and contradictory results found by different authors on dispersal evolution.

Evolution of Sex and Sexual Selection (1980)

If Hamilton’s obsession early in his career was the evolution of altruism, a recurring theme in his later work was the evolution of sex, one of the big outstanding questions in evolutionary biology due to its inherent costs as a reproductive strategy. From 1980 (Hamilton 1980) onward, Hamilton produced a series of papers examining the effect of fluctuations caused by antagonistic coevolution with parasites on the maintenance of sexual reproduction. But clearly these ideas had been on his mind for much longer. For example, in a 1975 book review (Hamilton 1975b) he stated, in relation to explanations for sex, that “...it seems to me that we need environmental fluctuations around a trend line of change. For the source of these we may look to fluctuations and periodicities inherent in our solar system, and also to the possibility of others generated by life itself.” Publication of these ideas was an occasionally frustrating process for Hamilton, and he admitted some bitterness about this in a refreshingly open and honest manner: “Unmistakably I harbour

a resentment toward some particular papers because they were readily accepted in a prestigious journal when one of mine wasn't. The acceptance there probably even colours my estimation of their content" (Hamilton 2001). Closely linked to Hamilton's work on sexual reproduction, the Hamilton-Zuk hypothesis (1982) is a model of sexual selection which posits that females choose mates with ornaments that indicate health, vigor, and resistance to parasites. Coadaptational cycles between parasites and hosts renew genetic variation and heritability of fitness.

Awards, Recognition, and Legacy

Despite the fundamental status that many of Hamilton's contributions now hold, the recognition of his work was not immediate. In the first decade after their publication, the two 1964 papers (Hamilton 1964a, b) were cited on average less than ten times per year, but within 15 years of its publication, kin selection had become a major theme in evolutionary biology (Grafen 2004). Richard Dawkins was greatly inspired by, and popularized, Hamilton's work when he championed the gene's eye view in his classic book, *The Selfish Gene* (Dawkins 1976). Later in his career, Hamilton was awarded a great number of prizes, medals, and honorary academy memberships, perhaps foremost among them the Crafoord Prize in 1993, which is often thought of as the biologists' equivalent to the Nobel Prize. Ranking scientists in order of importance may not be the most fruitful of tasks, but there is no doubt that Hamilton will be remembered as one of the foremost evolutionary theorists of the twentieth century.

Definition

Comparative analyses between (groups of) individuals from the same species.

Introduction

Within-species comparisons refer to comparative analyses between (groups of) individuals from the same species. These may be naturally occurring groups within the same population such as males and females (Gur and Gur 2017), or juveniles and adults (Adjorlolo and Egbenya 2016; Lobue 2009), or groups comprised of individuals varying in other behaviorally relevant characteristics (such as sociality, Ashton et al. 2018, or personality, Roche et al. 2016). Useful comparisons may also be made between geographically or temporally discrete populations of the same species. Such populations may vary culturally (Apicella and Barrett 2016; Luncz et al. 2018) or along relevant environmental gradients (Roth and Pravosudov 2009; Van Lange et al. 2017). Within-species comparisons also occur in experimental settings, with individuals randomly allocated to different experimental groups (Sulikowski and Burke 2015). In all instances, within-species comparisons have the potential to inform on the function, evolution, development, and/or mechanistic bases of behavior. In appropriate contexts they can provide more exact tests of phylogenetic and evolutionary hypotheses than can between-species comparisons (Sulikowski 2016). With the exception of their use in experimental designs, however, within-species comparisons are nevertheless limited in the extents to which they can support causal conclusions about behavior and its underlying mechanisms.

Comparisons Between Naturally Occurring Groups

Comparisons between naturally occurring groups within a population are probably the most common types of within-species comparison and are the types that most readily come to mind as the “typical” within-species comparison. Such comparisons encompass investigations into sex differences, age cohort effects, and social group effects. Studies involving these types of comparisons are classed as quasi-experimental,

since they involve comparisons between groups to which individuals *a priori* belong (as opposed to true experimental designs, in which individuals are randomly allocated to different groups).

Sex Differences

Sex differences in the brain and behavior are common in both humans and nonhuman animals (Gur and Gur 2017). These differences have proved important sources of data for evolutionary theories on a wide range of behaviors. While theories pertaining to reproductive behaviors are likely the most apparent beneficiary, sex differences have also informed evolutionary theories of foraging and perceptual priority. In this section I will use examples of these latter two applications to illustrate the broad utility of within-species male-female comparisons, for understanding the evolution of behavior.

Human sex differences in spatial cognition motivated the hunter-gatherer theory, which postulates that male advantages in allocentric navigation and female advantages in object location memory reflect the respective selection pressures on men and women, to optimize hunting and gathering efficiency (Silverman and Eals 1992). The hunter-gatherer theory does not purport to explain the totality of human sex differences in the brain and cognition but identifies one selection pressure – the need to maximize foraging efficiency – that would have applied differentially to the sexes. As men hunted and women foraged, differential selection pressures would have acted on the sexes to maximize foraging efficiency. By comparing men and women on a variety of tasks for which the hunter-gatherer theory predicts sex differences (including dead reckoning, Silverman et al. 2000, and proximal landmark-based navigation, Hughes et al. 2014), the extent to which selection pressures to maximize foraging efficiency are reflected in modern human cognition can be examined.

There is more information and stimuli available in the environment than any individual can attend to. As such individuals must allocate perceptual priority to some information/stimuli over others. Many studies have suggested that threatening, and other especially relevant, stimuli

are prioritized in this manner. However, studies that simply compare the speed of recognition and response to threatening and non-threatening stimuli are open to the criticism that some innocuous feature(s) of the stimuli, rather than their threatening status per se, simply render some classes of stimuli easier to perceive for stochastic, nonadaptive reasons (Quinsey 2013). In this context, sex differences between men and women in how attention is allocated to weapons (Sulikowski and Burke 2014) and to foods with sex-specific nutritional value (Love and Sulikowski 2018) can confirm that the relevance of stimuli to individuals drives prioritized attention (as these effects of sex cannot be solely attributed to idiosyncratic features of the stimuli used).

Age Cohort Effects

Comparisons between adults and juveniles of a species can speak both to the developmental trajectories of behaviors and to experiential impacts on behavioral phenotypes. For example, children under 6 readily conflate whether or not something is physically possible, with whether or not it is allowed, while adults clearly differentiate these concepts (Shtulman and Phillips 2018); and it isn't until after children are immunized (and have thus had an aversive experience with syringes) that they allocate prioritized visual attention to needles as a dangerous object (Lobue 2009).

Age cohort comparisons may also subserve more complex investigations, such as whether or not the same behavior appearing in juveniles and adults is supported by the same or different proximal mechanisms. For example, adult and older-adult sexual offenders tend to reliably exhibit executive function and intelligence deficits that distinguish them from non-sex offenders (Adjorlolo and Egbenya 2016), while juvenile sex offenders do not (Falligant et al. 2017). This implies that, for juveniles, sex offending is part of a broader pattern of delinquent behavior (Falligant et al. 2017), while in adults, it is indicative of sexually motivated behavioral dysfunction.

Sociality

Sociality has been proposed as one of the major evolutionary drivers of complex cognitive

abilities – the social intelligence hypothesis. Most evidence supporting this theory has derived from comparisons between closely related species differing in sociality. More recent support has come from within-species comparisons of Australian magpies, where individuals living in larger groups exhibit superior cognitive performance compared to individuals living in smaller groups (Ashton et al. 2018).

In cases where between-species comparisons provide the majority of evidence bearing on a theory, as is the case with the social intelligence hypothesis, within-species comparisons can be especially valuable. Between-species comparisons are always vulnerable to alternative interpretations: any given pair, or set, of species will vary along many dimensions, not just in the trait of interest. Bird species differing in social group size may also differ in any number of other traits (mating system, foraging ecology, predation risk, etc.), potentially confounding comparisons of cognitive ability between species with differing levels of sociality. Within-species comparisons of individuals living in differently sized groups can minimize many of the phylogenetic and ecological confounds associated with between-species comparisons providing, in this case, especially strong support for the social intelligence hypothesis (Ashton et al. 2018).

Comparisons Along an Environmental Gradient

How individuals and populations respond to environmental selection pressures (in terms of both behavioral plasticity and evolutionary change) is key to the adaptive nature of behavior. When a single species resides along an environmental gradient, whether continuously or in discrete populations, within-species comparisons along this gradient can reveal quantitative changes in the brain and behavior associated with the changing environment.

One large-scale example of human behavior change along an environmental gradient is the observed increase in violence and aggression associated with warmer climates. Some notable exceptions aside (including Russia and

South Africa, both of which are relatively far from the equator and exhibit high rates of violent crime), within and between countries, conflict and violent crime rates tend to be higher closer to the equator (Van Lange et al. 2017). This effect may be accounted for mechanistically by strong negative correlations between peripheral serotonin transporter density (low levels of which are associated with violence and impulsivity at the individual level) and ambient temperatures (Tiihonen et al. 2017).

A further example derives from the comparative literature. Black-capped chickadees occupy a large range across North America and rely heavily on supplies of cached food during the winter months. Accurate spatial memory, supported by the hippocampus, is required to recover these caches. As their range extends further north (away from the equator), the winters are harsher, and the birds are more heavily reliant on their cached winter stores. Comparisons of five populations of black-capped chickadees along this gradient of harshness revealed perfect rank-order correlations between both hippocampal volume and neuronal numbers, on the one hand, and increasing latitude on the other (Roth and Pravosudov 2009).

Within-species comparisons along environmental gradients take on a special significance in the context of global climate change. As temperatures rise, species will adapt (to the extent that they can, Butt et al. 2016). Comparisons along extant environmental gradients may reveal the capacities that different populations have to respond adaptively to increases in temperature and other associated climatic changes. They may also permit us to predict climate-induced behavioral changes at the population level. For example, mean increases in ambient temperatures of 2 °C have been predicted to result in a 3% increase in rates of violent assaults and murder across cold-temperate zones (Tiihonen et al. 2017).

Cross-Cultural Comparisons

Cross-cultural comparisons involve comparisons between groups of individuals from culturally

diverse backgrounds. They are frequently used both to examine the effects of cultural influences on behavior (Apicella and Barrett 2016) and also to identify those traits that are culturally invariant, especially with respect to people (Buss 2001). Cross-cultural comparisons also extend to nonhuman animals. In this domain, research is more strongly focused on cultural differences, since such differences provide the requisite evidence that divergent animal cultures exist (Luncz et al. 2018). Indeed, within the context of evolutionarily motivated investigations of behavior, the key difference between human and non-human cross-cultural investigations is that, with respect to the former, there is an accepted presumption that the behavior of individuals from very different cultures is likely to vary accordingly. As such, demonstrations of cross-cultural consistency and generalizability of findings are highly sought, as evidence of a genetic or biological basis for behavior. In the context of non-human cultural investigations, far greater emphasis is placed on demonstrating social transmission within a group of a behavior that varies between groups as evidence that cultural effects on behavior exist.

Cross-Cultural Comparisons in Humans

A classic cross-cultural comparison of human behavior is found with Buss' (1989) study which assessed 37 samples from 27 countries across 6 continents and demonstrated remarkable cross-cultural consistency in human mate preference sex differences: women more strongly prize traits indicative resource acquisition potential, and men more strongly prize traits indicative of reproductive capacity. Against the backdrop of the standard social science model (SSSM, Tooby and Cosmides 1992), which posits that within-group consistencies and biases in human behavior result from culturally constructed norms and societal influences, consistency across cultures of behaviors, whose supposed cultural determinants vary widely across those cultures, offers especially compelling evidence for the adaptive nature of human behavior. For example, very high cross-cultural agreement on subjective judgments of facial attractiveness (Langlois et al. 2000) undermines claims that attractiveness is a social

construct driven by the beauty ideals promoted in popular Western media.

The above is not to say that observed cultural differences in human behavior necessarily undermine evolutionary explanations of behavior. In fact evolutionary theories of behavior often predict cross-cultural differences. This often occurs in the context of predicting cross-cultural associations, at the level of the country between two or more variables. For example, Moore et al. (2013) report that women's preferences for facial cues of high testosterone are higher in countries with a low United Nations human development index and are also positively correlated with pathogen stress (at the country level). From this they suggest that women may facultatively adjust their preferences for male testosterone level, preferring more masculine male faces when environmental conditions are harshest.

Such conclusions about individual-level mechanisms drawn from group-level analyses, however, can be problematic. As Pollet et al. (2014) explain, there is no automatic concurrence of relationship between variables when measured at an individual, compared with at a group, level. To assume such a concurrence is known as the ecological fallacy. It is possible that two variables may correlate negatively across individuals within a group but positively across groups. Such a scenario is known as Simpson's paradox and has been empirically observed with respect to wealth and voter preferences in the United States. Within a state, wealthier individuals are more likely to vote Republican than Democrat, yet wealthier states are more likely to have a higher proportion of Democrat voters (Gelman et al. 2007). So while higher group-level associations can arise as a result of individual-level associations and mechanisms, without comparing both group-level and individual-level data, it is unwise to presume that the two will concur and have a common cause.

In the case of preferences for masculine faces in the face of environmental harshness, therefore, Moore et al.' (2013) country-level analysis, taken on its own, provides little convincing evidence of individual facultative responses to pathogens. However, other studies adopting experimental

techniques have observed increased preferences for masculine faces after exposing participants to cues of environmental pathogens (Little et al. 2011). This suggests that Moore and colleagues' conclusions may well be correct but multilevel analyses of individual-level data nested within country-level data would be needed to determine whether such individual facultative responses to pathogens are all that is driving the country-level association (Pollet et al. 2014).

Cross-Cultural Comparisons in Nonhuman Animals

Cultural traditions in nonhuman animals, observed as stable between group differences in socially transmitted behaviors, have most commonly been identified and studied in primate species, particularly chimpanzees (Luncz et al. 2018). Unlike in humans, where cultural impacts on behavior are taken for granted, demonstrations of cultural divergence of behavior in nonhuman animals are received more critically. In addition, nonadaptive, stochastic proliferation of culture is often presumed to be unique to humans, with animal cultural divergences presumed to be adaptive responses to environmental differences between groups (Boyd and Richerson 1988) arising from individuals within a group relying on individual learning to arrive the local optimal solution to a problem (Laland and Janik 2006).

More recently, though, it has been demonstrated that some local chimpanzee nut-cracking cultures are sub-optimal, using less efficient nut-cracking methods than those seen in neighboring cultures. Critically, this is true even of adult chimpanzee females who immigrated into a group from a group with a more efficient nut-cracking strategy. That these females choose to adopt the less efficient strategy of their new community rather than persist with more efficient strategies with which they are familiar implies a personal cost to the individual that must be outweighed by the benefits of conforming to group norms (Luncz et al. 2018). Such cross-cultural investigations in nonhuman animals are therefore revealing similarities between human and nonhuman animal social behavior that could support the development of

theories of nonadaptive cultural evolution and social conformity that are not anthropocentric.

Conclusion

Comparing how groups and individuals of the same species behave across different cultural, environmental, and social contexts and how behavior changes with age and sex affords tremendous power to understand the evolution, function, and mechanistic bases of behavior. When incorporated into experimental designs, they can support direct causal conclusions about behavior. Whether considering human or nonhuman animal behavior, within-species comparisons alleviate the confounds associated with between-species comparative analyses, providing more robust tests of the hypotheses at hand.

Women and Competition, The Oxford Handbook of

Maryanne L. Fisher

Department of Psychology, Saint Mary's University, Halifax, NS, Canada

Definition

An edited book that focusses on women and competition.

Introduction

The Oxford Handbook of Women and Competition was published by Oxford University Press in 2017 and edited by Maryanne Fisher. It contains 39 chapters, plus an additional introduction and conclusion. The chapters span a range of topics representing the current state of knowledge regarding women and competition. These chapters are organized into ten sections. The majority of the chapters pertain to intrasexual competition among adult women, although some contributors include girls and adolescents, as well as examining men in addition to women. Most, but not all chapters rely on an evolutionary framework. The goal of the editor was to provide a definitive volume on the current state of this area, as well as concrete directions for future research.

Book Overview

In the Introduction, the editor states that the goal of this book is to provide a definitive overview of the field of women and competition, as well as directions for new research. She outlines the reasons for focusing on women and competition and includes a brief historical outline of the academic development of this area. A short review of the contemporary state of the topic is provided. She presents areas that are still relatively neglected in the study of women and competition, including the determination of the ultimate motivations and

consequences of competition, mating competition among cowives as well as nonheterosexual women, acute and chronic health consequences of competition, competition that is outside of a mating context, competition across girls and women's life phases especially later reproducing or post-reproductive women, and individual differences.

The ten sections that follow the introduction address a wide range of topics. The first section, called "Theory and Overview" addresses general views of competition throughout women's lifespans, theory pertaining specifically to sexual competition, and, to provide a phylogenetic context, competition among female primates. The section on "Social Status and Aggression" reviews women's social status and network formation, adolescent reproductive competition, cooperation within social groups as a cause of competition, female friendships, and how we generally underestimate women's ability to deceive, harm, or manipulate others. In "Communication and Gossip," contributors first review how women may align their communication of aggression to environmental signals and competitors' individual differences. Then, they examine women's use of gossip for competitive purposes both in general terms, as well as specifically for mate poaching, for example, and the use of gossip as a form of informational warfare by coalitions. The section on "Mate Availability and Mating Relationships" covers issues such as the implication of imbalanced sex ratio (including operational sex ratio) on competition, the relationship between women's mate value and competition, competition among single and romantically partnered women, mate copying and poaching, and the positive consequences of romantic relationship dissolution, in terms of sharpening one's competitive skills. Contributors of the section "Endocrinology and Psychobiological Considerations" present the psychobiological (including hormonal) responses of competition, and further, the role of fertility via menstrual cycle phase on competition. In the section "Health and Aging," authors examine how competition often leads to sleep disruption and relatedly health, reproductive suppression and eating disorders, and competition in relation to women's age and parity. "Motherhood and Family" includes a comparative review of competition among mothers,

the advantages of the interaction of cooperation and competition in human mothers, conflict among family members with respect to mate choice, and women's progenicide. The section called "Physical Appearance" pertains to how women may opt to engage in beautification procedures and have elective cosmetic surgeries to compete, how and why they may participate in beauty pageants, and the use of fashion as a vehicle for competition. In "Competition in Virtual Contexts," contributors discuss how women may engage in competition with virtual rivals (such as those seen in advertisements), rely on social media as part of their competitions, or use computer games to hone their competitive skills. The section "Competition in Applied Settings" spans a range of topics, from the conceptualization of women's competition in the workplace, to women's use of food to compete, women's aesthetics and ornamentation as signals, and women's engagement and attitudes towards competitive sport and physical activity.

Last, in the conclusion, the authors discuss historic views of women, and how Darwin and Freud's androcentric thoughts may pervade modern researcher's perspectives on women and competition. They argue that recent developments in the area clearly indicates that women's competition is normal, rather than a deviation from a typical state of cooperation or inactivity. Moreover, they propose that women's competition is not inherently negative, and it does not reduce the importance or meaningfulness of friendships and family ties.

Conclusion

The Oxford Handbook of Women and Competition represents a thorough snapshot of the state of contemporary knowledge pertaining to this area. Moreover, concrete directions for future research are provided, with the intention of spurring novel yet important lines of inquiry. The chapters collectively demonstrate the significance of examining women's competition, and show, to varying extents, the ways in which women compete within their friendships, families, social networks, and with strangers. This book contains a wide range of theoretical perspectives on the motivations,

attitudes, and behaviors involved in women's competition, for the purposes of understanding how, when, and why women compete. Such competitions may be viewed in ultimate terms, such as competition over mates, status, dominance, and resources that influence one's children, or be more proximally oriented, such as toward winning a prize, such as a medal or scholarships. This book represents an important contribution to this growing area of research investigation.

Women Marry Up

Edward Dutton
Ulster Institute for Social Research,
London, UK

Synonyms

[Female hypergamy](#)

Definition

The phenomenon whereby women tend to marry men of a higher socioeconomic status than their own.

Introduction

There exists a stereotype that men are primarily attracted to looks while women are primarily attracted to status and wealth, meaning that, in terms of overall status, women tend to “marry up.” This is particularly obvious in instances where older men of considerable resources have relatively young and good-looking wives, such as

in the case of US president Donald Trump (b. 1946) and his wife Melania (b. 1970), a Slovenian model who is 24 years younger than him.

Female Hypergamy and Evolution

There is a large body of evidence that women tend to marry up (hypergamously) in terms of status to a far greater extent than is the case with men. This tendency for women to be more interested in the status, or the potential to gain status, of a potential partner has been shown to exist across cultures. Kendrick and Keefe (1992) have shown that females tend to be attracted to partners that are older than themselves, precisely because they are more inclined to sexually select for status and an older male is likely to have accrued more resources. Buss (1989) has demonstrated that across 37 cultures, women are more likely than men to value traits in potential partners that relate to “resource acquisition,” a characteristic regarded as much less important among men in their potential mates. It should be emphasized that there is much crossover with regard to the traits which males and females prize in potential partners (see Townsend and Wasserman 1998). Both sexes value personality traits such as honesty and kindness, for example, and there is a degree to which males are interested in the socioeconomic background of their potential partner. In addition, females are more inclined than males to select for attributes which may indicate that a man can protect them, such as height and muscularity (Buss 2003). Thus, sometimes females may select downwards socioeconomically or trade-off one aspect of status (such as income) for another (such as educational status) or trade status for physical attributes. But it is clear that, overall, there is a tendency for women to marry up in terms of status.

Buss (2003) has presented a plausible explanation for this finding. Men are more likely to select for signs of youth, health, and fertility, and thus for physical attractiveness, while women are more likely to select for signs of status or the potential to attain it. This is because the sexual relationship potentially incurs far greater cost for the woman

than for the man. The woman may become pregnant. With this mind, the woman and her offspring are more likely to survive if the male is prepared to invest in them and look after them. Accordingly, it makes sense for the female to select for a male who is likely to invest in her and who will have the resources to do so. So, we would expect her to select for indications of status to a greater extent than would the male, and we would expect females who had this inclination to be selected for and so more likely to pass on the genes. The male, by contrast, incurs much less cost from the sexual encounter, which would in principle make a strategy of simply mating frequently with large numbers of healthy women much more reproductively successful. As such, he is less inclined to select for status and more inclined to select for physical attributes such as facial symmetry, as markers of genetic health, and youth, as a marker of fertility. The result of this is that there is a tendency for women to marry down (hypogamously) in terms of physical attractiveness.

Female Hypergamy in Modern Societies

We might expect that the presence of increasingly sexually egalitarian societies in which females are increasingly financially independent of males might have the effect of altering these tendencies. The evidence indicates that the traditional tendency for female hypergamy remains across cultures and within relatively gender-equal societies (e.g., Rudman 2010), indicating that such tendencies have been selected for (see Buss 2003). For example, a survey of medical students by Townsend (1987) found that 85% of females believed that as their status increased their pool of potential partners decreased. Ninety percent of males believed quite the opposite.

In addition, more nuanced dimensions of status have been explored and the results have been found to be in the expected direction. For example, Dutton and Madison (2016) analyzed all marriages in Finland in the year 2013 between Finnish nationals and foreign citizens. They found that there was a greater tendency for Finnish women

to marry men from countries that were wealthier than Finland, whereas there was a greater tendency for Finnish men to marry women from countries that were poorer than Finland. They concluded that nationality is an aspect of status and it is something for which even modern European females are seemingly selecting. It would be fascinating if this could be replicated with marriage data sets from other countries.

Future Research

It would also be interesting for future research to examine the dynamics of status trade-offs within relationships. For example, a female university lecturer would have higher educational and social status than a male electrician or plumber, but she may well have a lower salary and thus lower economic status. Understanding the dynamics of these trade-offs is increasingly important when we consider that, in many Western countries, women are now more likely to go to university than men (Williams 2017), leaving many of them no option but to “marry down” in terms of educational status. Recent media reports have noted research finding an increasing trend whereby highly educated women, still single in their later thirties, freeze their eggs, with a view to attempting to have children later. An unpublished study of such women found that 90% had frozen their eggs to buy extra time to have children due to “a dearth of educated men” (Donnelly 4 July 2017). This could imply that, even among highly educated career women, the desire to marry hypergamously remains extremely powerful.

Consistent with this, it has been noted that in the UK, among the generation born at the end of the nineteenth century, there was a very high rate of spinsterhood among females from professional backgrounds. It has been suggested that the reason was the relatively high mortality rate of officers – as compared to troops – in World War I, with officers overwhelmingly coming from professional backgrounds. This meant that there was a pronounced dearth of high status males in relation to females after the War. The female refusal to

“marry down” thus resulted in noticeable levels of upper middle class spinsterhood in this generation (Nicholson 2008).

Conclusion

Female hypergamy can seemingly be found in all human societies and is underpinned by differential evolutionary pressures on females. They have been selected, to a greater extent than males, to be more interested in the status of their potential partner. Evidence that this phenomenon is indeed a matter of evolution can be found in its prevalence even in modern, sexually egalitarian societies.

[Faking orgasm](#); [Simulating orgasm](#)

Definition

Women acting as if they have experienced an orgasm when they have not, through vocalizations, breathing, body movements, muscular contractions, and/or verbal confirmation during the act.

Introduction

A substantial number of women (75–90%) do not consistently experience orgasm during sexual activity, and a considerable minority (5–10%) do not experience orgasm at all. Furthermore, when women do experience orgasm, it is typically in the context of masturbation or oral sex rather than penetrative sex (Brewer and Hendrie 2011). Despite the relatively low incidence of female orgasm during sexual intercourse, women frequently simulate orgasm through vocalizations,

breathing, and body movement. Indeed, a large proportion of women vocalize even when they are admit to having pretended a copulatory orgasm at least once in their lifetime (e.g., Kaighobadi et al. 2012; Séguin et al. 2015; Muehlenhard and Shippee 2010), and women who pretend to have orgasm are estimated to be at 13% of the time (Thornhill et al. 1995). Men are immensely interested in, and place great importance on, their partner's orgasm (McKibbin et al. 2010), though only 55% of men believe that they can identify when their partner is pretending to experience orgasm (Mialon 2012). Variability between women and across time may form part of the reason men are interested in copulatory orgasm, since women pretend orgasm more frequently when they have less consistent orgasm with their partner, suggesting that whether a woman pretends to experience orgasm or accurately signals orgasm may reveal important relationship information (Dove and Wiederman 2000). Interestingly, women whose partners ask if they have experienced orgasm are more likely to pretend orgasm, and over 50% of those who pretend orgasm report that they "feel guilty, but it is important to satisfy my partner" (Darling and Davidson 1986).

The variability in women's orgasms, along with men's intense interest in women's orgasms, may lead women to sometimes explicitly signal sexual enjoyment or orgasm when this is not experienced. For example, Brewer and Hendrie (2011) documented that while female orgasm occurs least frequently during penile-vaginal intercourse, more frequently during cunnilingus (receiving oral sex), and most frequently during masturbation, they also documented that the frequency of female sexual vocalizations (e.g., moaning, screaming) occurs in the opposite pattern. This pattern of orgasm vocalizations suggests that women sometimes embellish or fabricate orgasm cues. Indeed, a large proportion of women vocalize even when they are not experiencing orgasm (e.g., Brewer and Hendrie 2011). Further, women report faking orgasm more frequently than men perceive them to fake (Thornhill et al. 1995). Thus, women pretending orgasm is a common, deceptive copulatory

behavior, and researchers have only recently begun to illuminate the reasons and contexts surrounding this behavior.

Women's Reasons for Pretending Orgasm

A growing body of evidence suggests that female orgasm has one or more adaptive functions (e.g., sire selection via sperm retention, pair-bonding via partner satisfaction; see *Female Orgasm* for a review). For example, the most consistent predictors of female copulatory orgasm are partner's attractiveness and women's sexual satisfaction (e.g., Gallup et al. 2013; Sela et al. 2015). Ancestral men have likely attended to their partner's orgasm (reviewed in, e.g., Baker and Bellis 1995; Puts et al. 2012), perhaps as a way of increasing paternal certainty if orgasm facilitates conception (e.g., Baker and Bellis 1995), or because it increases relationship satisfaction and hence reduces the likelihood that women will seek extra-pair partners (e.g., McKibbin et al. 2010). Accordingly, men who are more invested and satisfied with their relationship are more interested in their partner's copulatory orgasm, and these associations are stronger for men who are at greater (vs. lesser) risk of partner infidelity (McKibbin et al. 2010). Men who are more satisfied with their relationship are more willing to invest in, and bestow benefits on, their partner (e.g., Shackelford and Buss 2000), providing an opportunity for women to gain more investment and commitment from their partner by increasing his satisfaction, perhaps by pretending orgasm.

Women consciously pretend orgasm to manipulate their partner's thoughts, feelings, and behaviors. For example, the vast majority of women (nearly 80%) report making copulatory vocalizations even when they know they are not going to orgasm (Brewer and Hendrie 2011), and women's most commonly endorsed reason for pretending orgasm is "I wanted to make my partner feel good about himself" (95% of the female sample; Séguin et al. 2015). Indeed, over 90% of women are confident that their vocalizations increase their partner's self-esteem (Brewer and Hendrie

2011), and about 90% report pretending orgasm for this purpose (Brewer and Hendrie 2011; Séguin et al. 2015).

Men place considerable interest in their partner's copulatory orgasm, though the extent of this may be related to their mate quality (Gallup et al. 2013) and to their partner's relationship satisfaction. Thus, a woman may pretend to orgasm in order to manipulate her partner into thinking that she perceives him to be of high mate quality and that she is sexually satisfied –making him believe that she is less likely to commit infidelity. Further, pretending orgasm may facilitate a dual strategy, whereby women maintain a long-term committed relationship and engage in short-term sexual relationships. Consistent with this explanation, women are most likely to pretend orgasm – thus displaying satisfaction with their partner – if they have previously engaged in sexual infidelity, if they anticipate that they will engage in future infidelity (Ellsworth and Bailey 2013), and if they signal sexual availability to other men (e.g., flirted with other men or neglected their partner at social gatherings; Thornhill et al. 1995). Consistent with this idea, men's concern about their partner's orgasm is positively associated with their perceived risk of her infidelity (McKibbin et al. 2010), and men react to discovering that their partner is pretending orgasm in a similar way as they do to discovering an infidelity (Shackelford et al. 2000).

Another advantage of increasing a partner's self-esteem via pretending orgasm is that he is more satisfied with the woman and their relationship, and this may be part of a broader mate retention strategy to reduce the risk of *his* infidelity. Mate retention tactics are behaviors used to keep a romantic partner from straying or being poached by a rival (Buss 1988; also see *Mate Retention*). Indeed, women who perform more (compared to less) frequent mate retention behaviors and women who perceive a greater (compared to lesser) risk of their partner's sexual infidelity are more likely to pretend orgasm (Kaighobadi et al. 2012). This is consistent with women's reports that they pretend orgasm to keep a partner from seeking extra-pair partners (Hite 1976). Further, risk of partner infidelity mediates the

relationship between likelihood of pretending orgasm and several mate retention tactics (Kaighobadi et al. 2012).

Another reason that women pretend orgasm is to manipulate a partner's orgasm timing. Cooper, Fenigstein, and Fauber (2014) report that stopping sex is an important motivation for pretending orgasm (e.g., "Because you want to stop sex but want to avoid your partner feeling uncomfortable in the future" and "Because you want to go to sleep"). Furthermore, 66% of women report using copulatory vocalizations to speed up their partner's ejaculation (Brewer and Hendrie 2011), and over 50% of women endorse "partner's orgasm seemed imminent" as an important reason they pretend orgasm (Séguin et al. 2015). Other advantages to women's ability to manipulate the occurrence and timing of a partner's orgasm may include lessening their risk of incurring physical damage from roughness, abrasion, and ensuing infection. Additional research is required to establish the physical benefits of manipulating male ejaculation.

Measures of Women's Reasons for Pretending Orgasm

Three scales assessing the reasons women pretend orgasm have been developed recently. Cooper et al. (2014) developed and validated the Faking Orgasm Scale for Women (FOS), with versions available to assess reasons for pretending orgasm during both sexual intercourse (i.e., vaginal sex) and during cunnilingus: the FOS – Sexual Intercourse scale contains 34 items assessing 4 factors: *Altruistic Deceit* (pretending orgasm out of concern for a partner's feelings), *Fear and Insecurity* (pretending orgasm to avoid negative emotions), *Elevated Arousal* (pretending orgasm to increase own arousal), and *Sexual Adjournment* (pretending orgasm to quickly end sexual intercourse). The FOS – Oral Sex scale contains 22 items assessing 4 factors: *Altruistic Deceit* (pretending orgasm out of concern for a partner's feelings), *Insecure Avoidance* (pretending orgasm to avoid feelings of insecurity), *Elevated Arousal* (pretending orgasm to increase own arousal), and

Fear of Dysfunction (pretending to cope with fear of being abnormal). Each FOS scale assesses the frequency of women's reasons for pretending orgasm on a scale of 1 (*Never*) to 5 (*Always*).

Séguin et al. (2015) developed the Motivations for Feigning Orgasms Scale (MFOS), which assess both men and women's motivations for pretending orgasm. The MFOS includes 25 items comprised of 6 subscales: *Intoxication* – high scores indicate that high alcohol consumption and/or drug use influenced the decision to pretend orgasm; *Partner Self-Esteem* – high scores reflect a desire to increase a partner's self-esteem or happiness by pretending orgasm; *Poor Sex/Partner* – high scores indicate that discomfort with a sexual partner, or lack of pleasure from the overall experience, influenced the decision to pretend orgasm; *Desireless Sex* – higher scores indicate that having sex without desire was an important factor in the decision to pretend orgasm; *Timing* – higher scores indicate that one's perception of a partner's orgasm timing influenced the decision to pretend orgasm; and *Insecurity* – higher scores indicate that feelings of insecurity with regard to oneself or the relationship influenced the decision to pretend orgasm. The MFOS assesses the importance of each reason in influencing the person's decision to pretend orgasm with a current partner (from the first time to the most recent time the person pretended orgasm with a current partner) on a scale of 1 (*Not at all important*) to 7 (*Extremely important*).

However, after conducting a confirmatory factor analysis, Séguin et al. (2015) demonstrated that their data was best represented by three models, each comprised of two or three factors: the *Pro-social Model* (Partner Self-Esteem and Timing), the *Get it Over with Model* (Poor Sex/Partner and Desireless Sex), and the *Feel Better Model* (Intoxication, Insecurity, and Improve Sex). These findings suggest that although they all lead to the same behavior, reasons for pretending orgasm may represent different sexual strategies and are perhaps sex-differentiated: women score lower than men on the Intoxication, Poor Sex/Partner, and Insecurity subscales.

McCoy et al. (2015) used the act nomination procedure and act frequency approach, to develop the Reasons for Pretending Orgasm Inventory (RPOI). The RPOI includes 63 items comprised of 3 components: *Improve Partner's Sexual Experience* – reasons that indicate an interest in increasing the sexual and emotional experience for the male partner and, to a lesser degree, for both partners; *Deception and Manipulation* – manipulative reasons such as hiding infidelity and exacting revenge; and *Hide Sexual Disinterest* – reasons that indicate desire to end a specific sexual event for lack of enjoyment. The RPOI assesses the frequency of women's reasons for pretending orgasm over the past month, on a scale of 0 (*Never*) to 9 (*Every time*), without specifying the type of sexual activity. The RPOI is currently being validated in a Brazilian context to further its utility as a cross-cultural measure (Lopes et al. in preparation).

Individual Differences in Women Pretending Orgasm

A number of factors may influence the likelihood that a woman will pretend to experience orgasm. Relationship factors are particularly important. For example, single women and women at greater perceived risk of (their partner's) infidelity are more likely to pretend orgasm (Darling and Davidson 1986; Kaighobadi et al. 2012) which may (falsely) signal sexual compatibility or relationship satisfaction in order to promote continuation of the relationship. Women with a greater number of lifetime sexual partners and those partnered to relatively low quality men are also more likely to pretend orgasm (Cooper et al. 2014; Wiederman 1997). This may serve to reassure men, concerned that his partner will engage in infidelity, that she is trustworthy. These men may (as a consequence) be less likely to engage in mate guarding, thus increasing opportunities for women to secure a high-quality extra-pair partner while minimizing the risk of discovery. This is consistent with previous research demonstrating that pretending orgasm is positively related to previous sexual infidelity and likelihood of future

infidelity (Ellsworth and Bailey 2013). Perhaps unsurprisingly, given the communicative and deceptive nature of pretending orgasm, women who believe that their partner can identify when they pretend to experience orgasm (without explicitly asking; Darling and Davidson 1986) are less likely to do so (Mialon 2012).

With regard to individual differences that are not relationship specific, women with higher levels of self-sexualization (which involves behaviors such as exposing one's body to gain sexual attention) and those holding the belief that sex can be a source of power (Erchull and Liss 2014) and women with higher sexual esteem (which reflects the tendency to evaluate oneself positively as a sexual partner; Wiederman 1997) are more likely to pretend to experience orgasm. Hence, in contrast to previous reports that pretending orgasm indicates female submission to androcentric society (e.g., Potts 2000), women may view the ability to pretend orgasm as a form of power or control. Indeed, there is a positive relationship between pretending orgasm and engaging in sexual behavior in order to attain a goal (McCoy et al. 2015). Furthermore, women with high levels of Machiavellianism, characterized by distrust, willingness to exploit others, and a manipulative interpersonal style, are more likely to pretend to experience orgasm in order to deceive and manipulate a partner. The association between Machiavellianism and pretending orgasm for this reason is moderated by relationship length, such that Machiavellianism exerts the greatest influence on women in long-term relationships (Brewer et al. 2016).

Conclusion

To conclude, female orgasm appears to have adaptive functions such as the retention of high-quality sperm, or strengthening of the pair-bond. Hence, men place considerable importance on their female partner's orgasm. Despite the apparent importance placed on female orgasms, these are not frequently experienced by women during penetrative sex, which may lead to a greater male interest in detecting and predicting them. Where

orgasm does not occur, women appear to sometimes strategically manipulate their partner's interest by pretending orgasm. Indeed, Nicolson and Burr (2003) report that women are less concerned with experiencing orgasm than often assumed, though women do wish to experience orgasm for the sake of their partner. This may take the form of vocalizations, body movements, altered breathing, or other such signals. The most common reason cited by women for pretending orgasm is to increase the partner's self-esteem, which may serve to strengthen the pair-bond and decrease the risk of infidelity and abandonment, resulting in continued access to resources and protection. Additional longitudinal research is required to establish the relationship outcomes (e.g., incidence or infidelity, relationship dissolution) associated with pretending orgasm.

Women Use Verbal Derogation to Be Included

Andrew M. Defever
Michigan State University, East Lansing, MI,
USA

Synonyms

Chastisement; Competitor derogation; Verbal aggression

Definition

Orally transmitted disparaging or negative statements targeting same-sex rivals for the purpose of reducing the target's perceived mate value.

Introduction

Associating with desirable same-sex friends – relational partners whose traits and characteristics can provide benefits to the self – may provide fitness benefits for women (i.e., increased access to desirable mates). However, such relationships can also be costly, most notably in the form of intrasexual competition. Women are known to engage in assortative selection of same-sex friends (SSFs) and peer relationships on factors such as personality, education, and attractiveness. However, having friends that are *higher* on these traits, particularly attractiveness, can foster intrasexual rivalry and competition. In response, women may engage in verbal derogation against SSFs and same-sex peers as a means of reducing the target's mate value in relation to the perpetrator, giving them a relative fitness advantage in intrasexually competitive domains.

Verbal Derogation as an Intrasexual Competitive Adaptation

Women's intrasexual competition for resources, such as access to desirable mates, is a well-documented phenomenon in contemporary social groups. Within these contexts, including SSFs, women may utilize indirect aggression in order to gain a fitness advantage against their same-sex rivals. One such tactic is verbal derogation or the deployment of negative and disparaging statements against a target competitor. This derogation is commonly directed towards a target's physical appearance or sexuality, that is, traits that are highly valued by the opposite sex in the appraisal of one's mate value (MV). Such statements are designed to suppress the perceived attractiveness or sexuality of the target in an attempt to decrease

their relative MV and give the perpetrator a competitive advantage (Baumeister and Twenge 2002).

Evidence that women may possess adaptations for monitoring threats that SSFs pose to their mate value and subsequent mating opportunities comes from research demonstrating that women can reliably estimate their own MV and that of another. For example, when a woman perceives that a SSF is more attractive than her, it increases perceived mating rivalry (Bleske-Rechek and Lighthall 2010). Furthermore, research demonstrates that women are particularly intolerant of attractive peers. Women perceived as attractive and who display signs of sexual availability are known to be the target of more indirect aggression from other women (Vaillancourt and Sharma 2011).

These effects are stronger when the perpetrator is in the fertile window of their menstrual cycle, when conception probabilities are highest. It is during this time that women stand to make the greatest gains in reproductive fitness from increasing their mating appeal relative to other women. Subsequently, during these time periods women are more likely to compete with each other for the most desirable mates and are more likely to implement derogative strategies such as rating other women as less attractive (Fisher 2004).

There are also costs associated with employing verbal derogation tactics. Fisher et al. (2010) found that those who employ verbal derogation towards another are perceived as less friendly, less attractive, and have a reduced MV. This may be, in part, why women employ indirect aggression (such as gossip) more than direct or physical aggression, as it allows for plausible deniability and a defense against culpability for the implementation of verbal derogation tactics. However, despite the potential costs associated with such tactics, verbal derogation is effective in its ability to disparage competitors, as shown by victims' reduced self-esteem, increased anxiety and depression, and (in severe cases) self-harm or suicide (Vaillancourt 2005). Inasmuch as intrasexual rivals who experience these negative outcomes are less effective competitors and/or are perceived to have a reduced MV, this provides

evidence for a distinct fitness advantage to the perpetrator.

Conclusion

Women's verbal derogation of SSFs and same-sex rivals, particularly during peak fertility, allow them to increase their relative MV and accrue fitness benefits within intrasexually competitive contexts. Although costs may be accrued by those who are caught employing such tactics, the prevalence and effectiveness of verbal derogation among SSFs denotes its continued utility toward increasing fitness during intrasexual competition.

Definition

Main strategies used by women from intrasexual competition to retaining the selected mate.

Introduction

According to the Sexual Strategies Theory (Buss and Schmitt 1993), women and men rely on short-term and long-term strategies for reproductive purposes. Women consistently prefer to secure long-term mates rather than engaging in short-term mateships. To secure long-term relationships, women use specific strategies in both selecting and retaining a romantic partner. Self-promotion and derogation of rivals are the most widely used higher-order strategies that women use in

intrasexual competition, long-term mate attraction, and mate retention in romantic relationships.

Men's Mate Preferences Form Women's Competitive Strategies

The fundamental components of Darwin's (1859) theory can be summarized as variation, selection, and retention. In a mating context, *variants* are the potential mates, *selection* refers to processes which lead to reducing the number of mates to few or one, and *retention* refers to strategies used to retain the selected mate (Buss 1988). After writing "On the Origin of Species," Darwin (1871) expanded on the natural selection theory and specifically on the second component, which is selection. He proposed that in the second phase of natural selection, certain characteristics are evolved in some organisms to help them compete with their same-sex rivals and capture the opposite-sex attention. This concept has been referred to as *intrasexual selection*. Opposite sex's attention mostly is captured by survivors of the "competition" and prefers the fittest mate with certain desirable characteristics that is called *intersexual selection*.

Intrasexual selection and intersexual selection have an asymmetrical association. Preferences of one sex should affect competitive strategies used by the opposite sex (Buss 1988). For example, men from different cultures typically prefer women with physical attractiveness, facial attractiveness, youth, and feminine features. Hence, women use certain strategies to gain or augment these desirable characteristics and acquire a high-quality male partner for long-term relationships. In short, many of the preferences men consistently show for women are based on reproductive outcomes and are directly related to a woman's mate value. Men throughout the world show a larger preference for women who are physically attractive, healthy, and facially symmetric, as these traits are indicators of the woman being able to successfully bear healthy offspring (Buss 1989). Men also have been shown to prefer youth because youth indicates a higher reproductive value. In addition, men also prefer someone who

is somewhat mature and creative, with a preference for a slow life history as this suggests that the woman would be around for long term and able to contribute to the children's long-term well-being.

Fertility, senescence of reproductive organs, social status, physical strength, emotional stability, and abilities to acquire reproductively relevant resources are among the well-established preferences that men and women place emphasis. These characteristics are core to association values, such as kin value and coalitional value. These characteristics also play an important role in mate value and make age central to human mating. Cross-cultural studies show that humans appear to have universal mate preferences, including those for the age of potential mates (e.g., Buss 1989). Such preferences were originally hypothesized to function in guiding people to adaptive mate choices, a fundamental domain of life for sexually reproducing organisms. However, they also should have implications for a considerable number of downstream behavioral outcomes, such as tactics of attraction, selection of mates as a function of mate value, determinants of mate retention behavior, probability of divorce, and a number of other important life outcomes.

Long-Term Versus Short-Term Strategies

There are hypotheses claiming that even if women engage in a short-term mating, it is in line with their long-term strategies and there are potential benefits for such acts. Symons (1979) drafted the Resource Accrual Hypothesis (i.e., in which female ancestors earned meats, goods, or services through a short-term extra-pair mating), and Better Genes Hypothesis (i.e., in which the woman copulates with another male other than her own long-term mate to bear a child with better genes). He also suggested mate Expulsion Hypothesis (i.e., women use short-term copulation in order to break up with their long-term mates easier) and Revenge Hypothesis (i.e., when women participate in short-term affairs as a vengeance for their husband affair). Honing Mating Skills Hypothesis suggests that, unlike men, women's objective when attending short-term mating is to enhance

their sexual, attraction, and seduction skills. According to Self-esteem Hypothesis, women can also use it to increase their self-esteem to be able to make better decisions for a long-term mating. Additionally, Buss and Schmitt's (1993) Preference Clarification Hypothesis of women's short-term mating is that they use it to assess if their short-term mate is a potential long-term one. Preference Clarification Hypothesis claims that women use short-term mating to shed light on their long-term decision processes. Furthermore, Commitment Hypothesis suggests that a short-term mating for a woman is a way to increase her partner commitment by evoking his jealousy. Mate Switching Hypothesis proposes short-term mating is a way to find a more valuable long-term mate.

Ever since Sigmund Freud who suggested that people look for the characteristics of their opposite-sex parent in a romantic partner, and the emergence of the complementarity theory (i.e., needs of each mate are different in kind and intensity and they are complementary instead of similar). To Thiessen and Gregg (1980) who considered similarity as the main reason why we choose certain mates, to Berscheid and Walster (1974) who proposed exchange and equity theory in which people seek for mates with whom they can exchange resources until a proximate equivalence in exchange has reached (Buss and Schmitt 1993). These different theories on human mating share two common notions. They developed their theories in a long-term context. However, none of the aforementioned theories point out that forming a long-term relationship is a strategic process. These theories claim that humans should seek for equity, similarity, and complementarity, but they do not specify the mating processes according to gender differences. They also do not specify which strategy is applicable for each sex. What are the strategic goals for each sex? What do women look for in a potential mate and likewise. These theories propose a single process, which shows who should mate whom (Buss and Schmitt 1993). Nevertheless, mating preferences change according to the context. Buss and Schmitt (1993) recommended Sexual Strategies Theory which articulates human mating is strategic and

humans look for a mate through whom they can dissolve adaptive problems their predecessor faced. Strategies are different according to the mating context, gender, and the mating temporal stability (short-term vs. long-term). Gender is a major axis in sexual strategies theory because biologically humans are different. For example, women fertilization is cyclical and internal, and after one act of intercourse, they are pregnant for 9 months. Temporal stability is the other major dimension of sexual strategies theory. Humans have evolved long-term mating strategies to solve the problem of commitment, long-term pair bonding, and parental investment (Buss and Schmitt 1993).

Benefits of Long-Term Mating for Women

By using certain long-term strategies, women tend to solve: (1) the problem of noticing a potential mate capable of investing, (2) the problem of noticing a potential mate who is actually willing to invest, (3) the problem of gene quality, (4) the problem of commitment, (5) problem of good parenting skill, and (6) the problem of physical protection (see Buss and Schmitt 1993).

Women try to solve the first three problems through winning intrasexual rivalry. It is an evolved adaptation in which women notice the potential mate with desirable characteristics (e.g., masculinity, physical attractiveness, symmetry, and intelligence) and the necessary resources for successful reproduction and assess his interest in a long-term mateship (Darwin 1871). Regarding these problems, Trivers (1972) suggested the *parental investment theory* which is defined as "any investment by the in an offspring that increases the offspring's chances of surviving" (Trivers 1972, p. 139). He also suggested that the more one sex invests in progeny; the more that sex will be discriminating. The more investing sex is typically the female, because she is pregnant for 9 months, then she bears the child, and she lactates the child for 2–4 years (Trivers 1972). Male resources benefit the woman and the children, but the male infidelity will divide his economic

and energy resources, which is not beneficial for the female at all. If defecting from the committed relationship, males' resources will be taken away from the female and her offspring toward an intrasexual rival (i.e., another female). Hence, women have adapted certain strategies to solve the second three problems (i.e., problem of good parenting skills, problem of physical protection, and problem of commitment). When pregnant and breastfeeding, women are vulnerable. Over our evolutionary history, women were in danger of food scarcity and being a target for aggressive perpetrators. A long-term mate could prevent these when the female is vulnerable and provide them with protection and nourishing food. Such long-term mate would also invest in the offspring and stay in the relationship to take care of the children. Women try to perform certain strategies to retain their long-term mates in order to stay safe from physical harm caused by opposite-sex violence or same-sex rivals and keep their mate committed to her and the offspring (Buss 1988).

Buss (1988) classified the strategies women and men use to retain their long-term mates. His classification rated mate retention strategies in a range from acceptable behaviors (e.g., vigilance toward mate's behaviors) to socially unacceptable behaviors (e.g., violence toward same-sex rivals). Later these strategies were classified into two domains of Benefit-provisioning strategies and Cost-Inflicting strategies. Benefit-Provisioning strategies try to reduce partner's infidelity likelihood by elevating relationship satisfaction and Cost-Inflicting strategies try to reduce likelihood of partner's infidelity by lowering partner's self-esteem (Miner et al. 2009).

Among all the mate retention strategies, women prefer low-risk and less physically aggressive strategies in their long-term mating. After the child is born, the presence of mother is more vital for the child's survival. A mother is the primary caregiver and lactates the child for 2–4 years. Women specially have evolved more interest in long-term mating and their reproductive success depends on the resources, which a potential long-term mate can provide them and their children (Buss and Schmitt 1993).

Women's Self-promoting Strategies

According to sexual strategies theory, the evolved mate preferences in one sex are the characteristics over which the opposite sex competes (Buss and Schmitt 1993). Perceptual mechanisms are evolved to circumvent problem of identification quality of a potential mate. Physical and behavioral characteristics associated with youthfulness are indicators of a woman's reproductive ability and men's mate preference. Beauty standards vary in different cultures and what is physically attractive in a culture can change over time. However, human societies have agreements on some aspects of beauty. For example, across cultures women's beautiful appearance is important both for males and for females. Additionally, men prefer their potential mate to be younger than themselves and attractive. Younger women are more preferred by men for a long-term mating because they represent productivity (Buss 1989).

Women's intrasexual and intersexual competition mostly circles around their physical and facial attractiveness. Attractive women are more probable to marry and have children. Hence, women's mate retention behaviors also circle around their beauty and they try to make their appearance seem young, attractive, and reproductively valuable (Buss 1988). They use self-promotion strategy to increase their partner's satisfaction and decrease possibility of infidelity. This strategy ergo is related to the characteristics that are preferred by men. Self-promotion is proposed to be most effective mate retention strategy for women (Buss 1988).

In this strategy, women manipulate their physical and facial characteristics on purpose and promote them deliberately. They use different strategies to enhance their physical and facial attractiveness in order to both select and retain a long-term mate (e.g., dress, jewelry, cosmetics, exercising, dieting, weight loss, skin tanning, and tattoo). Women cut off other costs, just to spend more on cosmetic products. They dress up and wear makeup, which can be considered as "traditional" appearance enhancement behaviors (Haselton et al. 2007).

Dieting, exercising, and desire to lose weight is another way to enhance appearance. Women are more worried about their weight when exposed to thin rivals and when primed with intrasexual competition, mating motives, and mate retention motives; they are more probable to use dieting pills and try to lose weight. Women also believe skin tanning enhances their appearance. Skin tanning can conceal skin imperfections, scars, and cellulite (Buss 1989).

According to recent advances in cosmetic surgeries, new techniques to promote appearance are available (Atari et al. 2016). Cosmetic surgeries can artificially promote appearance that is an indicator of good genes and fertility. The number of different cosmetic surgeries is increasing and this can be attributed to sociocultural and media pressures on women to obtain standards of beauty (Atari et al. 2016). For example, women can elevate their attractiveness by changing their waist-to-hip ratio (WHR) through a cosmetic surgery. WHR is one of the mate preferences for men and an indicator of their fertility. Women's interest in cosmetic surgeries is associated with their preference for many resources in the potential long-term mate (Atari et al. 2016). It is also positively associated with low self-perceived attractiveness, body dissatisfaction, intrasexual competition, perfectionism, envy, media influence, and menstrual cycle (e.g., Kalantar-Hormozi et al. 2016). Women interested in cosmetic surgeries prefer their long-term mate to be resourceful, attractive, educated, and intelligence (Atari et al. 2016). Overall, women who use Benefit-provisioning mate retentions report higher consideration of cosmetic surgery (Atari et al. 2017).

Women's Rival-Derogating Strategies

Women's success in intrasexual competition leads to attracting mate and derogating rivals. However, the procured mate should be retained over time. Derogating rivals is another strategy that is beneficial in intrasexual competition and retaining the acquired mate. This strategy also focuses on characteristics that are preferred by the opposite sex. Except in this strategy, women depreciate the

values of same-sex rivals. Men are evolved to prefer attractive young women with indicators of fecundity (low waist-to-hip ratio, full hips, and large breasts). When attending to invest a long-term relationship, they prefer a mate with sexual fidelity (Buss 1989). Hence, women aim to derogate their rivals over aspects of their physical characteristics (weight, body size, and facial characteristics) and sexual history. By disclosing information about the derogated rival, men will be less willing to form a long-term relationship with the targeted women because they perceive it is more possible that a promiscuous woman is sexually unfaithful. At the same time, derogator is suggesting that she will remain faithful in a long-term relationship. Derogating the rivals in such ways increases the derogator's self-esteem and increases the chances of a long-term romantic relationship for her. By using this strategy, derogators advertise herself to her current or potential partner (Fisher and Cox 2009). Derogation of rivals is a noncombative strategy in which women try to enhance their positive characteristics and bold them for their long-term mate compared to same-sex rivals by using verbal derogation of rivals and social manipulation (Buss and Dedden 1990).

Throughout evolution, women have acquired the ability to notice any signals sent from rivals to their existing mate. They try to keep their mate away from any sexual signals sent by rivals. For example, if competitors are wearing revealing or provocative clothes, women try not to introduce their mates to such rivals and they use statements like "boobs were about to pop out," "what is she wearing," and "she is dressed as if she wants to have sex with her professor." They also found that when wearing provocative clothes, women try to derogate other women compared to when they were conservative clothes (Vaillancourt and Sharma 2011). Women try to derogate the rival and reduce their value and in result, men find the derogated female less attractive (Fisher and Cox 2009). Derogation of rivals is specifically verbal in women and toward any signs sent from the rivals or any value that the mate prefer in a partner. They try to derogate the rival's appearance, loyalty, and sexual history. However, when using verbal

derogations, women should carefully devalue the rivals because they do not want their mate to think they are mean or inconsiderable (Schmitt and Buss 1996). Fisher et al. (2010) studied the effects of derogating a rival's physical characteristics, personality characteristics, and sexual history on men's perception of the derogator. Result indicated that men's view about derogator's personality desirability decreased. Hence, derogation of rivals remains the second strategy for women and they prefer to try appearance enhancement as their first long-term strategy (Fisher et al. 2010). They derogate rivals to promote their self-esteem and advertise themselves (Fisher and Cox 2009). Overall, derogation of rivals is a socially unaccepted strategy and is one of the "cost-inflicting" strategies among mate retention behaviors.

Gossip is a form of evaluative discussion about a third person. In an evolutionary context, gossip is another psychological adaptation in which values or flaws of a third person who is embedded within complex social networks are exchanged (McAndrew and Milenkovic 2002). Gossip has been studied both in individual and group level. A group prefers to talk about same sex negative features and devalue their physical, facial, and personal characteristics. Bromley (1993) also suggests that one of gossip's usage is reputation manipulation. Gossip is an intrasexual competition strategy and a mate retention strategy. It is a form of derogation of rivals, used more by women. Women use gossip for competitive social comparisons. They have greater interest in sharing and taking part in a gossip whether it is positive or negative. It is expected that women try to solve the adaptive problems they face and the content of women's topic should be different from men's gossip. Additionally, gossip content varies according to population density, availability of mates, and number of same-sex rivals (Walsh and Yun 2016). When exposed to an attractive rival, women's jealousy is provoked and they find negative gossip about that rival an indirect way to express their jealousy (Wert and Salovey 2004). On the other hand, women may find negative gossip about a potential mate and transmit it to same sex rivals in order to throw them off of the scent. Women prefer not to gossip about their

mates, they do not talk about their friends or relatives, and they easily recall the gossip about potential rivals mating skills (De Backer et al. 2007). Additionally, women can share the content of the gossip with both their partners and same-sex friends, but men prefer to share their gossip with their romantic mate not their male friends (McAndrew et al. 2007). When the gossip comes from an attractive mate with high values, it is an effective way to derogate same-sex rivals.

Overall, younger women and attractive women with higher values are more interested in gossip. It is also worth noting that frequency of gossiping does not have any association with women's relationship status because single women try to derogate rivals by gossiping about them with potential mates and mated women need to perform this strategy to retain their mates (Massar et al. 2011). Women can use these two long-term strategies concurrently (i.e., derogation of rivals and appearance enhancement). They can make themselves desirable by wearing makeup and revealing clothes and at the same time derogate a rival by gossiping about their sexual history, appearance, or social standing with their long-term partner. However, the gossip must be subtle and it should not point any weakness that the derogator herself has (e.g., gossiping about a rival's too much makeup while wearing one herself) (Campbell 2004).

Other Strategies Women Use in a Long-Term Relationship

Although Cost-Inflicting mate retention strategies cannot predict women's consideration of cosmetic surgery, but research shows that there is a positive association between women's consideration of cosmetic surgery and six specific mate retention strategies: vigilance, monopolization of time, punish mate's infidelity threat, derogation of competitors, physical possession signals, and possessive ornamentation (Atari et al. 2017). Women avoid losing their long-term mate by threatening to leave them and by verbally proclaiming their long-term relationship with their mate to others and rivals. These strategies explain women exhibiting relational

aggression more than men (Campbell 2005). Women also threaten their partner by claiming to be sexually unfaithful which is why men place more importance in partner's sexual fidelity compare to women (Schmitt 2005).

Women's long-term strategies help them to solve the adaptation problems they face. One of women's adaptation problems is selecting "good genes." When copulating with attractive men (i.e., attractiveness is an indicator of "good genes"), it has been shown that women experience more frequent orgasms compared to women who copulated with less attractive men (Shackelford et al. 2000). Orgasm in ovulation elevates chance of conception. A woman's pregnancy encourages the partner investment and commitment (Thornhill and Gangsted 2008). Women are more likely to pretend orgasm during copulation. Women reported reasons for pretending an orgasm. One of the reasons was to keep the mate committed to his current relationships and reduce the likelihood of relationship dissolution (for a review, see Muehlenhard and Shippee 2009). Women who pretend an orgasm perform mate-retention strategies more frequently (Kaighobadi et al. 2012).

Conclusion

Overall, women employ a number of long-term strategies in mate attraction and mate retention (Chaudhary et al. 2018). Men's differential preferences in long-term mating drive women's intrasexual rivalry which can be reduced to self-promotion (e.g., appearance enhancement) and rival-derogation (e.g., gossip about rivals' promiscuity). After securing a long-term dependable partner, long-term strategies do not diminish. Women (usually less frequently than men) use a number of mate retention strategies to keep their romantic partner around. Factor analytic and clustering techniques have revealed that such behaviors can be categorized into cost-inflicting (e.g., violence against rival women who show interest in one's husband) and benefit-provisioning (e.g., cosmetic surgery as a beautification procedure) tactics.

Synonyms

Female mate interests; Female partner preferences; Women's mate interests; Women's preferred partners

Definition

The qualities that women are interested in when selecting partner's for short- or long-term relationships.

Female Mate Preferences

Introduction

Within evolutionary psychology, the study of women's mate preferences is a central and important topic. This chapter will discuss the general strategies that women tend to use when looking for a mate. Following this, there will be an overview of what is known about female mate preferences, focusing on three major features known to be most important in women's mate preferences: a man's face, his body, and his behavior. The chapter will conclude by covering several contextual factors that can cause women's mate preferences to shift in predictable ways.

Mating Strategies

In almost all species, including mammals, males and females differ in how much they invest in their offspring in terms of time, resources, and energy. The ultimate evolutionary force is maximizing the number of offspring that live to reproduce and extend an individual's genes into future generations. According to Parental Investment theory (Trivers 1972), the sex that makes greater initial investments in offspring ought to be the "choosier" sex when it comes to mate preferences and mate standards. In humans, females must make larger initial investments in offspring than men because females gestate, lactate, and provide most of the basic care of infants at the beginning of their lives.

Many studies have documented differences between men and women in their general mating strategies, usually consistent with parental investment theory. Women, for example, tend to have lower sex drive than most men, they desire fewer sexual partners and want longer-term relationships, and they are more likely to regret past sexual encounters. This is consistent with the notion that women – because they invest more in offspring – are choosier about when and with whom to have sex, and they value partners who will be committed to them and their children. These presumably evolved differences in mating strategies should also affect the types of mates that women prefer. Across 37 cultures, Buss (1989) found that women favor men who are more capable of acquiring resources (e.g., larger amounts of

money, higher social status) presumably because such men can better provide for offspring, increasing the likelihood that offspring will survive to reproductive age. These effects, however, also depend on the roles of women in relation to men within a given culture. Eagly and Wood (1999) reanalyzed the 37 cultures data and found that these sex differences are smaller in societies that have more egalitarian views of men and women and when women hold greater social, economic, and/or political power in a society.

Women also prefer mates who want longer-term commitments, most likely because such men are more able and willing to provide long-term resources for their children. However, there is considerable variation within women in these and other mate preferences. According to Gangestad and Simpson (2000), women evaluate potential mates on two basic dimensions: (1) a man's resources and ability to be a good long-term provider and (2) evidence of him having "good genes" (signaled by his health, attractiveness, and related cues), which could be passed on to offspring. There will now be a discussion of the mate qualities women should have evolved to prefer in a man's face, body, and behavior, as well as the contextual factors that tend to alter what most women prefer in mates.

The Face

Three aspects of the face are believed to signal the quality of a man's physical condition or his "good genes": symmetry, averageness, and sexually dimorphic features. Humans tend to be bilaterally symmetrical, with the left and right sides of their bodies being similar in size and proportion. If, however, individuals encounter disturbances during development (e.g., they have deleterious genetic mutations or are exposed to environmental toxins or pathogens), their bodies become somewhat asymmetrical as they grow. Greater facial and body symmetry, therefore, should be viewed as more attractive because greater symmetry indicates that an individual has withstood these disturbances better than others across development.

Facial averageness is also perceived as attractive in mates, because it is another possible marker of good genes. Average facial features tend to

reflect the normal (nondeleterious) genes that exist in a population. Thus, the more a face differs from the population average, the more a person is likely to possess genetic mutations or other defects that might impair his or her successful reproduction.

Sexually dimorphic features are physical qualities that evolved differently between the sexes. Men, for example, have more facial hair, more prominent brow ridges, and are more muscular than women, on average. Sexually dimorphic traits are indicative of a man's level of testosterone and, therefore, his ability to attain and maintain social status and be a good resource provider. Now there will be a review of studies that have examined how women view these theoretically relevant facial features when evaluating men as potential mates.

Facial Symmetry

Facial symmetry is a quality that is attractive in both men and women, and it is believed to be an indicator of overall health. Indeed, greater facial symmetry in men tends to be associated with greater social dominance and better reproductive health as well as more facial averageness and more sexually dimorphic (masculine) features (e.g., Fink et al. 2001; Van Dongen and Gangestad 2011). Swaddle and Cuthill (1995), however, found that if the mean size of certain facial features was held constant, the connection between greater facial symmetry and higher rated facial attractiveness was eliminated, suggesting that the average size of certain facial features may partially explain why symmetrical faces tend to be more attractive.

Facial Averageness

The first evidence suggesting the greater attractiveness of average faces came from computer simulations in which faces were morphed together to create composite faces. As the number of faces in a composite increased, so did their perceived attractiveness (Langlois and Roggman 1990). Morphed faces are usually rated as more attractive than virtually all of the individual faces used to create a composite (Rhodes et al. 2001). Although average male faces are viewed as slightly less

masculine than distinct faces, they are perceived to be healthier and may be an honest signal of health quality.

Sexually Dimorphic Features

A large amount of research has investigated the attractiveness of sexually dimorphic (more masculine) characteristics of male faces, which include a longer lower face, more facial hair, and more prominent brow ridges and cheekbones. Greater facial masculinity is known to be associated with higher testosterone levels (Penton-Voak and Chen 2004). Along with facial averageness and symmetry, more sexually dimorphic facial features increase how healthy women perceive men to be and how healthy they actually are (Thornhill and Gangestad 2008). There is debate, however, about whether and when masculine faces are preferred in mates. Some studies have found that men who have more feminine faces are preferred in certain mating contexts. These findings may be attributable to either the specific features of the face being manipulated or the morphing techniques used. In addition, as highlighted later, preferences for more masculine features tend to fluctuate with changes in the environment, especially where a woman is in her menstrual cycle.

Facial hair is another sexually dimorphic trait that affects female mate preferences. Neave and Shields (2008) had women rate men who had no beard, a light stubble, or a full beard and found that as beard length increased, so did the male's perceived dominance and aggression. Women were most attracted to an intermediate beard length (a light stubble), at least in younger men.

The Body

A man's body also provides cues to the quality of his genes and/or his status within a society. Female preferences for different features of male bodies may have been shaped by selection pressures, leading women to value certain attributes. Similar to beard length, intermediate levels of muscularity are most attractive to women, on average (Frederick and Haselton 2007). Moderate muscularity tends to signal better health, whereas too much muscularity is costly to both develop

and maintain, hindering health. Other important body features are the width of a man's shoulders relative to his hips and height. Women typically prefer men who have a higher shoulder-to-hip ratio, and such men have more sex partners and engage in first sex at an earlier age (Hughes and Gallup 2003).

Women are also attracted to men who are taller. Fink et al. (2007) investigated how the ideal height of a partner shifts based on a person's own height and found that relative height was more important to attractiveness than total height. That is, women who are shorter than average find slightly shorter men (who are still taller than them) more attractive. One explanation for this preference is that height may be a cue to a mate's status in society. Indeed, if a man is taller, he is more likely to have more wealth and resources.

Another cue that women consider is the quality of a man's voice. Male voices that have lower fundamental frequencies and men who have larger vocal tracts are perceived as more attractive mates (Feinberg et al. 2005). Attraction to these vocal features might be explained by the link between voice pitch and testosterone levels, with deeper voices signaling higher testosterone, which may be another marker of higher status and/or genetic quality.

Behavior

In addition to physical appearance, there are certain male behaviors that women may have evolved to prefer in potential mates, because they are cues of a man's social status and/or his genetic quality. One cue is the amount of social dominance exhibited by a man. When trying to attract a romantic partner, men often try to demonstrate feats of strength or behave aggressively toward other men during competitive tasks. Women are also more likely to feel negatively about their current romantic partner and relationship when they are shown alternative partners who have more dominant personalities (Kenrick et al. 1994). However, women do not derogate their current partner and relationship after seeing physically attractive alternative partners, which suggests that social dominance is a powerful, independent behavioral cue.

Although dominance is important, women also consider other personality traits when selecting mates. Jensen-Campbell et al. (1995) had women observe a male who displayed either high dominance, high agreeableness, both, or neither. High dominance led men to be rated as more attractive, only if men were also high in agreeableness. Men who were low in agreeableness were rated as less attractive, regardless of their level of dominance. Other studies have found that men who display kindness to women, but dominance to other men, are perceived as most attractive by women. These findings are consistent with the premise that women evolved to find displays of male dominance attractive, most likely because they are indicative of a man's social status. However, women are *most* drawn to men who direct aggression and dominance toward other men, decreasing the chance that such men might pose a threat to their female mates.

Risk-taking is another behavioral tactic that men use to attract mates. Skateboarders, for example, perform riskier tricks (with an increase in both successes and failures) when they are being observed by an attractive female experimenter than by an attractive male experimenter (Ronay and von Hippel 2010). Importantly, men observed by an attractive female had higher levels of testosterone, which were assessed immediately after they had performed tricks in front of the female experimenter.

Engaging in certain risk-taking behaviors should have been evolutionarily adaptive because ancestral women may have been more likely to mate with men who took calculated risks, especially if the outcomes were successful. Very little research, however, has examined whether and how women perceive different types of risky behaviors enacted by men. One study (Petratis et al. 2014) asked women to rate the attractiveness of men who were taking two types of risks: "modern-day" risks (e.g., not wearing a seat belt) or risks faced by our ancestors (e.g., handling/dealing with wild animals). Women rated men who took more risks as more attractive but only if those risks were in the ancestor category. Attraction to certain risk-taking behaviors enacted by men may have been beneficial to women in

ancestral environments. Men who engaged in greater risk-taking may have been generally more successful at obtaining necessary food or resources needed for survival or at fending off adversaries.

In sum, women typically prefer men who are more socially dominant (but kind toward them) and who engage in some degree of risk-taking. Nevertheless, one must also take the broader social and environmental context into account to gain a more complete and accurate picture of female mate preferences. These contextual factors will now be discussed.

The Context

A growing body of research has begun to address how contextual variables influence female mate preferences. Three contexts shape a woman's attraction to potential mates: the general environment in which she lives; her local, social, and interpersonal environment; and where she is in her menstrual cycle (the fertile vs. infertile phase) when evaluating potential mates.

General Environment

The general environment in which a woman lives provides important contextual information that can alter her mating strategies and, therefore, affect her mate preferences. One important environmental variable is the local operational sex-ratio (i.e., the number of men relative to women seeking mates in a population). When there are more women and men in a population, the tendency to engage in short-term relationships and have more sexual partners increases, because men, being fewer in number, can act on their short-term mating tendencies. Moreover, when there are more men in a society, a man's socioeconomic status becomes much more predictive of his marital status, with higher SES men being more likely to marry (Pollet and Nettle 2008). Conversely, when women have more potential mates to choose from (i.e., when women are in the mating minority), they become choosier and prefer mates who have more resources to offer.

Another important variable is the amount of pathogens in the local environment. In pathogen-prevalent environments, the threat of disease is

higher, particularly for young children. In such environments, women ought to value indicators of a man's genetic quality more than his status or resources, given that "good genes" may protect subsequent offspring from the threat of disease. Indeed, women who live in environments with more pathogens value a man's physical attractiveness more than they do in low-pathogen environments (Gangestad and Buss 1993). Moreover, making the threat of pathogens salient to women shifts their mate preferences in theoretically consistent ways. Women who view information emphasizing high-pathogen prevalence shift their mate preferences to men who have more masculine characteristics and are more symmetrical compared to women who view cues of low-pathogen prevalence (Little et al. 2011).

Resources and a woman's access to them is another set of environmental factors that can affect female mate preferences. In societies that are more egalitarian with respect to gender issues, the mating preferences of men and women are more similar (Eagly and Wood 1999). Nevertheless, women who live in high socioeconomic status areas are more attracted to men who have a larger shoulder-to-hip ratio, whereas women in low SES areas prefer men who have a higher body mass index (Swami and Tovée 2005). These results are consistent with the notion that women evolved to prefer male traits that would have facilitated the survival and eventual reproduction of their offspring. A woman who has higher social status is likely to have enough resources to protect and provide for her children, so obtaining "good genes" should be prioritized and cues of physical strength should be valued, whereas a woman who has lower social status should prefer men who demonstrate their resource acquisition potential.

In sum, the broader environment in which a woman lives does shape her mate preferences. The operational sex-ratio in the local environment, cues of pathogen prevalence, and environmental demands that increase the importance of providing resources shift whether a woman's mate preferences focus on pursuing men who have "good genes" versus those who can provide sufficient resources to her and her offspring.

Local Interpersonal Environment

Mate choice also takes place within a woman's local interpersonal environment, which influences with whom she interacts, her relative mate value, and the resources to which she does or does not have access. When examining women's preferences for warmth, attractiveness, and status in a mate, women who rate themselves as high in a specific category (e.g., warmth) are more likely to have higher and less flexible ideal standards for that category (Campbell et al. 2001). Women who believe they are more attractive also prefer characteristics such as greater facial symmetry and more sexually dimorphic features in mates. These and other results imply that women who are more desirable tend to adjust their mating strategies to attract the most desirable male partners. When there are more partners to choose from, women are in a better position to obtain men who score higher on all important qualities, and when the pool of available mates is smaller, their standards are lowered.

Whether a woman wants a short-term or a long-term relationship is another important determinant of what she finds attractive in a mate. When a woman is interested in a short-term relationship, markers of genetic quality are more important and more masculine facial and body features are preferred (e.g., Little et al. 2002).

Another critical interpersonal variable is incest avoidance. Children born to parents who are biologically related (e.g., cousins) are more likely to have physical abnormalities and health problems due to the inheritance of recessive genes. Accordingly, people rely on environmental cues to determine with whom they might be genetically related. The length of time a female has lived with a male during childhood and how much time the male has spent with her biological mother both decrease how attractive a man is to a woman, because these cues are associated with the likelihood of being biologically related (Lieberman et al. 2007).

Both the general environment and the interpersonal environment can influence a woman's mate preferences in significant ways. Many of these effects, however, are qualified by whether

women are in the fertile versus the nonfertile phase of their menstrual cycle.

Menstrual Cycle

Two phases of a woman's menstrual cycle tend to have different effects on her mate preferences: (1) the follicular (fertile) phase and (2) the luteal (nonfertile) phase. The follicular phase ends with ovulation, the time when having sex is most likely to result in a pregnancy. During the luteal phase, the chances of conception are much lower.

Women should have evolved to shift their mate preferences depending on the probability of conception (Thornhill and Gangestad 2008). Specifically, women should be more attracted to men who display indicators of "good genes" when they are looking for a short-term relationship rather than a long-term commitment. Consistent with this idea, when preferences for facial features are examined, women in the follicular phase are more attracted to men who have more masculine features compared to women in the luteal phase, suggesting that where a woman is in her menstrual cycle may partially explain some past mixed findings (Penton-Voak and Perrett 2000). This shift in preference toward more masculine features has also been demonstrated with more masculine voices and greater facial symmetry.

Where a woman is in her cycle also affects the specific behaviors she finds attractive in men. For example, socially dominant behaviors are significantly more attractive to women who are in the follicular phase (closer to ovulation) than in the luteal phase (e.g., Gangestad et al. 2004; Cantú et al. 2014). A recent meta-analysis confirmed that these shifts in attraction are fairly consistent when women are pursuing a short-term mate while ovulating (Gildersleeve et al. 2014).

Conclusion

This chapter has reviewed a wide variety of findings about the qualities that most women prefer in a mate. Early research focused primarily on the general preferences that women report. More recent research has focused on within-person variability in mate preferences and the specific

environmental contexts that moderate (shift) these effects. Although more is now known about women's mate preferences and the evolutionary logic behind them, more research is needed to clarify how these evolved preferences affect established romantic relationships across time.

Women's Mate Retention Tactics

► Women's Long-Term Strategies

Women's Mate Value

Cassandra D. Beck and John E. Edlund
Rochester Institute of Technology, Rochester, NY,
USA

Synonyms

Mate quality; Quality of a “catch”

Definition

Mate value is the construct that broadly describes one's value as a mate to a potential or actual partner.

Introduction

Mate value is a construct that is thought to holistically measure the value of an individual as a mate (Edlund and Sagarin 2014). Although many measures of mate value use similar methods of assessing men's and women's mate value, research has demonstrated that there are differences in the qualities men and women seek in a mate (although it is worth noting that many similarities exist as well). For instance, research has shown that men seek youth, physical attractiveness, facial attractiveness, and feminine features in their partners (Buss 1989). These preferences have been demonstrated worldwide (Schmitt 2005), and this independently suggests that these traits directly contribute to a woman's mate value.

Reproductive Value

Another reason to think that youth, facial attractiveness, and feminine features relate to women's mate value is the concept of reproductive value. Reproductive value is an estimate on the number of future children a person is potentially able to have moving forward in time, and it is one of the main pressures contributing to women's mate value (Barton and Etheridge 2011). Importantly, the previously identified traits contribute to women's reproductive value. Unlike men's reproductive value which does not rapidly decrease with time, a woman's reproductive value is always decreasing from the time she starts menstruation (as high quality eggs get released and are not replaced). A woman's reproductive value reaches zero with the onset of menopause (whereas a man's reproductive value does not have a corresponding zero value). As such, youth, physical attractiveness, and beauty constitute an important part of women's mate value.

To illustrate this concept, in a budgetary task of American undergraduates designing their ideal partner, men and women designed very similar ideal mates for themselves, only showing slight gender differences in certain areas. The men considered attractiveness to be necessary in a mate, whereas women put emphasis on resources

(Edlund and Sagarin 2010). Additional research suggests that men believe the ideal age for a woman is just under 25 years old, which corresponds to women's peak fertility (Buss 1989). This also suggests that men prefer women who are more likely to have a stable life before pursuing the idea of children.

Physical Attractiveness

As mentioned earlier, another factor that contributes to women's mate value are feminine features. Perhaps the most important feminine feature is the waist-to-hip ratio. In women, waist-to-hip ratio represents an evolutionary cue that a woman is capable of carrying and bearing children to term. This, along with physical attractiveness, serves as an important marker of mate value. A study by Fernandez et al. (2014) found that younger women compete more fiercely amongst themselves to increase their mate value, whereas older women do not compete as much. Fernandez et al. also found that in order to increase their mate value, women have become cognizant of their Body Mass Index (BMI). Their research suggests that BMI has an effect on mating success in women, therefore implying that the type of physical attractiveness men seek in women is related to a woman's ability to maintain a healthy body.

Another factor that directly contributes to the mate value is facial symmetry, or the degree to which one side of the face is similar to the other side of one's face. Grammer and Thornhill (1994) found that facial symmetry in addition to feminine features were indicators of physiological and genetic health. Grammer and Thornhill's research was based off of the parasite theory, which suggests that sexual selection looks for traits that display resistance to parasites. It has been found that organisms that are parasite resistant are not only healthier, but also are more successful in the competition for mates. Therefore, men who seek women with facial symmetry and feminine facial features are likely finding women who are parasite resistant (and therefore a higher mate value).

Other factors such as life history also are thought to contribute to mate value. Life history

is the physical and social growth across a life-span that can be limited by the accessibility of resources that may be assigned to various tasks or goals. Individuals who have a slow life history (where an individual lives in a stable environment and is able to finish schooling and is able to obtain a quality job) are viewed as having a higher mate value than those with a fast life history (Dillon et al. 2013). Among the things that a slow life history is associated with is how physically attractive an individual is perceived as (such that people who have a slow life history are seen as more attractive).

Conclusion

In short, many of the preferences men show for women are evolutionarily based and are directly related to a woman's mate value. Men throughout the world prefer a woman who is physically attractive, at a healthy BMI, and who are symmetric, as these traits are indicators of the woman being able to successfully bear healthy children. Men also have been shown to prefer youth because youth indicates a higher reproductive value. Yet, men also want someone who is somewhat mature and creative, with a preference for a slow life history as this suggests that the partner will be around for long term and able to contribute to the children's long-term success.

Introduction

This entry provides a brief overview of research about associations between women's economic resources and their long-term partner preferences. These associations are of special interest in light of women's tendency to attribute more importance to financial resources in a partner than men do (Buss 2011). Whether this pattern is a result of evolved adaptations, sociocultural factors, or some combination of the two continues to be a subject of controversy. Evolutionary psychological theory stipulates that female reproductive success depends on resources necessary to raise offspring. Hence, women should prefer partners with an ability to invest direct resources in offspring, resulting in a preference for good financial prospects (e.g., Buss and Schmitt 1993). From a sociocultural view, pervasive gender inequalities make women more likely to adopt domestic rather than provider roles. To compensate for the limited resources associated with domestic work, women seek out mates with good economic prospects (e.g., Zentner and Eagly 2015).

Women's Movement

► Feminism

Women's Personal Resources

Marcel Zentner
University of Innsbruck, Innsbruck, Austria

Synonyms

Family roles; Gender equality; Income; Pay equity

Definition

Material assets (e.g., income, property) owned by women.

Hypotheses

Drawing from these premises, the two theories make different predictions about the role of women's own financial resources in their long-term partner preferences. According to evolutionary psychologists, women's preference for financially secure men is an evolved adaptation and should therefore be impervious to their own financial resources (Buss 2011). From the standpoint of sociocultural theory, women's dependence on men for resources should diminish as their own financial autonomy increases, thus lessening their emphasis on a mate's financial prospects. Evaluating the empirical merits of diverging assumptions in research on mate preferences requires consideration of evidence from multiple domains, in which mate preferences of women and men vary in major ways: (a) across cultures, (b) across historical periods within the same culture, and (c) across individuals (Zentner and Eagly 2015). In what follows, I will review and integrate

some key findings from each of the respective research literatures.

Cross-Cultural Research

Cross-cultural studies can examine whether national differences in Gross Domestic Product relate to the importance women attribute to their future partners' financial prospects. More important than absolute levels of wealth, however, is women's access to resources relative to men's. This ratio is captured by gender equality indices. Gender equality tends to be associated with a decrease in the importance women place on partner earnings relative to men and in absolute terms (see Zentner and Eagly 2015, for a summary). The size of the association varies depending on the measures of gender inequality used and the classes of control variables included. In general, associations tend to be stronger when comprehensive measures of gender inequality are used, such as the relatively recent Gender Gap Index (Zentner and Mitura 2012), and weaker when narrow measures of gender equality are used, such as the Gender Empowerment Measure (Conroy-Beam et al. 2015).

Historical Trend Analysis

Trends over time provide a second source of information about associations between women's own financial resources and the importance they attribute to earning prospects in a partner. In most nations, the pay gap between women and men has gradually diminished over the last decades. This is largely attributable to women's increasing participation in market work. As a result, women have become financially more autonomous. From an evolutionary psychology viewpoint, progress towards pay equity should have little effect on women's partner preferences. From a sociocultural view, one would expect this development to reduce the importance that women attribute to a partner's earning prospects.

The available data on mating preference across time are limited because they rely on US

replications of a particular survey of preferences initially administered in 1939, with follow-ups conducted at regular intervals up to 2008. Comparisons across follow-ups are difficult before 1985, when ratings of mate preferences were added to rankings (Boxer et al. 2015). Between 1985 and 2008, women's annual income as a percentage of men's increased from 65.2 % to 77.1 % (*The gender wage gap 2012*; Institute for Women's Policy Research, 2013). Women's importance ratings for financial prospects did not change during this period. However, women's importance ratings for favorable social status, intelligence, or ambition (all features indicating resource acquisition potential according to evolutionary psychology theory) did show a declining trend over the same period (Boxer et al. 2015).

Individual Differences Research

A third research approach capitalizes on the large variation in mate preferences between women of a given culture. The question addressed by studies using this strategy is whether differences in women's economic resources are systematically related to differences in the emphasis that these same women attribute to financial prospects in a partner. Although some earlier studies reported a *positive* correlation between women's financial resources and their preference for wealth in a partner (see Buss 2011, for a summary) more recent studies did not (e.g., Anderson and Klofstad 2012; Fales et al. 2016). A large-scale study that, in contrast to earlier studies, used a nationally representative sample of 4,790 US citizens is particularly informative. Participants were asked about their annual income (categorized from under \$25,000 to \$150,000 or more), as well as the importance they attributed to a partner "making at least as much money as they do" (Fales et al. 2016). The relationship between own income and income desired in a partner was $\beta = .07$ for women and $\beta = .03$ for men. The interaction between sex and income was not significant, indicating that the association did not differ by sex. In a larger but nonrepresentative sample of visitors to the NBC News website

examined by the same authors, the relationships were similar ($\beta = .07$ for women and $\beta = -.01$ for men). Similarly immaterial were the associations in another large-scale study ($\beta = .04$), and they did not differ between the sexes (Anderson and Klofstad 2012).

Explanations and Interpretations

The absence of a link between women's financial status and the importance they place on partner earnings in correlational studies has been interpreted as evidence contradicting sociocultural models and supporting evolutionary reasoning by some scholars (Buss 2011). However, such a conclusion is not warranted for there are several alternative explanations. Methodological issues could have led to the weak or contradictory findings, such as differences in the use and understanding of terms such as "resources," "earnings," or "income." It is also possible that different subgroups of women exhibit contrasting tendencies or that conflicting psychological factors are at work, both of which would result in neutralization of effects.

For instance, allocation of time to housework versus market activities (paid employment) remains highly uneven across the sexes, including in societies with comparatively high levels of gender equality. This phenomenon has been attributed to the persistence of gender roles, notably the male breadwinner norm (Zentner and Eagly 2015). This norm may constrain the mate preferences of financially independent women. Though in principle predisposed to value men for their homemaker qualities, some of them may be hesitant to express and act on this preference to avoid undermining their male partner's sense of masculinity. As a consequence, they may seek out men with even greater earning capacity or remain unmarried. In support of this possibility, a Danish study found that husbands whose wives outearned them were more likely than other husbands to use erectile dysfunction medication (Pierce et al. 2013).

In turn, other women might be less sensitive to prevailing gender norms. For instance, one study

reported a negative relationship between feminist attitudes and the importance placed on good earning potential in a partner (Koyama et al. 2004; see also Eastwick et al. 2006 for a similar result). Thus, women who are not constrained by traditional gender roles do not seem to place particular importance on their partner's earnings. Somewhat concordant with this proposition is evidence that decreased preferences for earning potential in a partner are related to women's *control* over resources rather than resources per se (Moore et al. 2006).

Another type of evidence pointing to opposing trends neutralizing each other is people's general tendency to seek out partners who are similar to themselves across a large variety of attributes (including background, lifestyles, values, and personality traits). This "similarity-attracts" effect has been attributed to factors such as propinquity and the self-validating effects of familiarity (Günaydin et al. 2013). The pervasive, non-specific similarity preference may override any intention of financially independent women to seek out men for with homemaker qualities rather than for their earnings prospects.

To evaluate the empirical merits of this explanation, one must dissociate any specific similarity preference related to financial resources from an unspecific similarity preference. Student populations are suited to this end because the limited variation in lifestyle, values, and background characteristic of student populations will constrain generic "similarity-attracts" effects. In experiments using such student populations, women's mate preferences for financial prospects have been shown to change as a function of their anticipated role and income. In one experiment, female students who were led to envision a future as a stay-at-home parent preferred a partner with provider qualities, whereas women led to envision a future as an employed parent preferred a partner with domestic skills.

In a related experiment, the wealth of a partner was more valued by participants when they were asked to envision themselves living in a long and difficult economic crisis as opposed to a period of prosperity and well-being. The induced experience of scarcity made a wealthy partner look

more desirable, regardless of the participant's sex. These studies suggest that women's specific preferences for earnings in a partner are geared towards maximizing the type of support that they would be denied in virtue of their anticipated future role (see Zentner and Eagly 2015, for a review of these studies).

Conclusion

Taken together, the studies reviewed for this entry suggest that economic opportunities and constraints do affect women's mate preferences. Women's financial resources have been found to be negatively associated with the importance that they attribute to men's resources in certain types of studies, notably cross-cultural and experimental studies. The evidence from studies across time is less conclusive. Studies based on analyses of individual differences do not show a negative correlation. The negative association could be absent, or it may exist but be occluded by a non-specific attraction for similarity, social norms related to family roles, or a combination of both. Findings are also difficult to interpret for another reason. Most studies have used relatively crude measures of income as indicators of women's personal resources. In so doing, important distinctions between classes of resources have been overlooked (assets, property, income, wealth, or debt).

Conclusion

The evolutionary hypothesis of women's preferences for material resources in a mate is neither clearly contradicted nor is it supported by evidence about the role of women's personal resources in their mate preferences.

Women's Preferences During Ovulation

Kelly Cobey

Ottawa Hospital Research Institute, Ottawa, ON, Canada

Department of Psychology, University of Stirling, School of Natural Science, Stirling, Scotland

Synonyms

Conception risk; Endocrine changes; Fertility; Human estrus; Menstrual cycle; Mid-cycle

Definition

There is evidence to suggest that women's mate preferences diverge across their menstrual cycle; such changes likely relate to hormone fluctuations required to support ovulation.

Introduction

A growing literature, spanning a number of academic disciplines, including psychology, cognitive sciences, and medicine, has demonstrated that women's preferences, behavior, and physical appearance vary as a function of their menstrual cycle phase (reviewed in Gildersleeve et al. 2014). This literature is consistent with a previously established and parallel body of work documenting cyclical shifts in preferences and

physical appearance in nonhuman primate species. In nonhuman primates overt sexual swellings and changes in attractiveness in proximity to ovulation are termed “estrus” signals. Based on the fact that human females do not experience overt sexual swellings, and that they are sexually receptive throughout the cycle, many scholars initially believed that a “human estrus,” akin to that which occurs in primates, did not occur. However, less conspicuous changes in attractiveness and preferences, analogous to those that occur in nonhuman primates, are indeed present in proximity to ovulation when conception risk is greatest. This discovery was made in the 1990s (e.g., Gangestad and Thornhill 1998), and intense interest was subsequently generated for this phenomenon. This interest may in fact be a consequence of the fact that shifts were not initially obvious and that they appeared difficult to explain without use of an evolutionary perspective.

Evolutionary Explanations for Changes in Women's Preferences Across the Menstrual Cycle

Gangestad and Thornhill (1998, 2008) introduced the Ovulatory Shift Hypothesis as a potential adaptive explanation for the presence of these shifts. The Ovulatory Shift Hypothesis argues women experience a dual sexuality, where the preferences they display when in proximity to ovulation diverge from those that occur at other cycle phases. This divergence in preferences is thought to be adaptive because it focuses women's attention on physical traits and behaviors of potential male partners who have what are considered “good genes.” That is, women can make use of male phenotypic traits that are thought to signal genetic quality when discriminating between mates. As a consequence, increased attention to, and preference for, “good gene” partner's when conception is most likely could increase the likelihood of conceptive sex with such individuals, thereby increasing the likelihood of producing children with heritable traits of good genes (Folstad and Karter 1992). The Ovulatory Shift Hypothesis specifically postulates

that preferences for “good gene” traits should be more significant for short-term, as opposed to long-term, mating contexts. Importantly, the changes in cognitive perception and preference for putative “good gene” are predicted to be subtle (i.e., nonconscious).

Evidence for Changes in Women's Preferences Across the Menstrual Cycle

Over the past two decades, numerous studies have been designed to test the assumptions of the Ovulatory Shift Hypothesis, most of which have provided broad support. For example, near to ovulation, women show stronger preferences for masculinity or dominance in male faces, voices, bodies, and scents. Women also show stronger preference for symmetry in male faces and bodies (reviewed in Gildersleeve et al. 2014). A more restricted body of literature has also tested, and found evidence for, the idea that women show increased preference for more dominant competitive male behavior and use of courtship language when in proximity to ovulation. Evidence that women prefer higher levels of creative intelligence in proximity to ovulation provides additional suggestion that indicators of mental fitness are also preferred at higher rates by women at this time (reviewed in Gildersleeve et al. 2014).

Evaluating Research Designs of Studies on Women's Preferences Across the Menstrual Cycle

Taken together this evidence base appears robust; however, there are a number of methodological shortcomings that are important to consider. Firstly, the link between the proposed phenotypic indicators of “good genes” has been called into question (e.g., Scott et al. 2013). Ultimately, it appears more research is needed to determine what heritable advantage women achieve by pairing with men who display higher levels of masculinity, dominance, symmetry, and related traits. Secondly, the vast majority of published studies on this topic have taken place in controlled laboratory settings, often making use of using forced choice paradigms, where female participants are asked to choose between two sets of computer-generated stimuli modified from a

single male participant. This situation is rather contrived and the external validity of these designs is therefore low. While a few notable exceptions to this exist, overall few preferences have been tested in designs with strong external validity, and even in controlled lab environment effect sizes from studies are relatively small (Gildersleeve et al. 2014). This begs the question of whether or not shifts in women's preferences, or in their own attractiveness and behavior, across the cycle, have any impact for social relationships (Cobey and Buunk 2012). Havlicek and colleagues (2015) recently proposed the Spandrel Hypothesis as an explanation for changes in women's attractiveness across the menstrual cycle. This hypothesis can also be extended to changes in women's mating preferences across the menstrual cycle. They argue that changes across the cycle may be a by-product of a more general mechanism. That is, if hormones underpin women's preferences for particular male traits, women with particular hormonal profiles, such as high estrogen, would have stronger preferences than women with other profiles, such as relatively lower estrogen. So, if hormones underpin shifts in preferences, shifting preferences may be incidentally related to menstrual cycle stage since women's hormones vary across the cycle. These within-woman hormonal shifts are substantially smaller than the baseline or absolute differences in hormonal levels between women, and as a consequence these within-women effects are smaller. Currently this proposal requires empirical testing, but it provides a fruitful starting point for future work.

Variation in Methods Used to Assess Women's Menstrual Cycle Phase

A further methodological concern in relation to the evidence base for the Ovulatory Shift Hypothesis is that measures of ovulation, or assessment of proximity to ovulation, have generally been very crude. It is perplexing, but proximity to ovulation or conception risk, the variable at the center of the Ovulatory Shift Hypothesis, has not been clearly defined, and many measures exist. We know that menstrual cycle length varies between women, with anywhere between 21 and 45 days being

considered normal (Hornstein and Schwerin 2013). In spite of this, many researchers compare women's preferences and behaviors using broad cycle phases, and assume these differ in conception probability, without actually assessing hormones or underlying physiological mechanisms to confirm women's conception risk at these measurement points. This strategy often termed "the counting method" sees researchers counting forward, or backwards, from the date of menstrual onset to a prespecified and discrete "fertile window." An assumption is made that the days in the selected "fertile window" reflect a phase of "high fertility" relative to the days outside of this window that are considered to be "low-fertility" phases. Interestingly, the "fertile window" chosen varies between published papers (Wood et al. 2014), but 6–9 day windows are typical. The reverse counting method considers the fact that the luteal cycle phase, the phase of the cycle that occurs after ovulation, tends to be less variable than the follicular phase of the cycle, which occurs before ovulation (Fehring et al. 2006). While this method would help to reduce variation, many researchers opt to use the forward counting methods, or even estimates of next menstrual onset, as these can be more practical when scheduling participants to take part in studies. Indeed, early studies on this topic used between-participant designs to ease the burden of participant recruitment. Fortunately, as the field moved forward, within-subject designs began to dominate the published literature.

Some groups of researchers use luteinizing hormone test strips to assay conception risk of female participants in their studies. While use of LH test strips are preferable to a total absence of hormonal measures, one issue with this validity of the argument is that in spite of a detectable LH surge, anovulation is possible. Moreover, we know that LH increases in a pulsatile fashion, that some women have multiple surges within the same cycle, and that the time on the LH surge may be before, after, or during ovulation (Direito et al. 2013). One option to circumvent this issue is to use transvaginal ultrasonography to assay proximity to ovulation (e.g., Cobey et al. 2013), though this is likely only feasible

through broad cross-disciplinary collaboration. This method, while highly accurate in determining conception risk, does not speak to the underlying hormonal mechanisms that govern any effects documented (see section on hormonal mechanism below). An excellent analysis of the issues surrounding the assessment of conception probability in the ovulatory cycle was recently provided by Gangestad and colleagues (2015), who simulated more than 58,000 cycles and concluded that aside from methods that count backwards from the confirmed date of menstrual onset, the validity of typical counting methods and LH assays used in this area are at best modest.

Mechanisms and Semantic Concerns in Research Examining Women's Preferences Across the Menstrual Cycle

The use of terms like "high fertility" and "low fertility" to describe two distinct phases of the menstrual cycle, while commonplace in this literature, are problematic because they fail to accurately relay that conception risk across the cycle is in fact a continuous measure. The title of this entry "Women's preferences during ovulation" (assigned to me) erroneously implies that ovulation is a distinct menstrual cycle phase. Rather, ovulation is a physiological process that occurs in an instance, which is initiated by hormonal changes. Thus, ovulation itself is not a mechanism that could produce shifts in women's preferences. These semantic issues are important as they reflect broader (mis)understanding in physiological processes occurring across the menstrual cycle and how these are subsequently used in hypothesis generation.

Research that assays a broad range of ovarian hormones across the menstrual cycle, as well as their interactions, is needed to clarify the mechanisms that underpin shifts in women's preferences documented across the menstrual cycle. Only recently has work considering hormonal mechanisms been published (see Hahn et al. 2016 for discussion). As work in this area progresses it will be important to consider hormonal variation in short-term interactions and ultimately the role neurotransmitters play in regulating these effects.

Conclusion

In spite of the methodological shortcomings associated with many of the studies describing menstrual cycle shifts in women's preferences, the consensus of reviews in this area is that the shifts are a robust phenomenon (Gildersleeve et al. 2014; for a critical view see Wood et al. 2014). To contribute meaningful progress to research on the topic of women's preferences across the menstrual cycle, at this point, rigorous studies using within-women designs, power analyses to determine sample size, and measures of endocrine hormones to assay underlying mechanisms are desperately needed. It is only when these types of studies are conducted that knowledge in this area will progress. While it may be more costly to design studies to achieve this standard, the reduction in bias that these designs afford may be well worth the investment. It appears we need less research, but better research: This could be achieved through the initiation of collaborative research projects and pooling of research funds. Consideration of the evolutionary value of shifts in preferences across the cycle, even if they are shown to be robust in less bias designs, remains (Havlicek et al. 2015).

Female strategies; Prosociality; Social hierarchy;
Social status

Definition

Females display a sex-specific pattern of expressions of dominance, which is a universal feature of human psychology.

Introduction

Dominance is a common strategy for achieving social influence across social species, including among humans. Dominance can be defined as the use of aggression, threats, fear, and intimidation to attain and maintain disproportionate levels of influence within a social group (Barkow 1989), and evidence suggests there are important sex differences in the expression of dominance (Buss 1981). Among sexually dimorphic species, females are often at a disadvantage concerning dominance-based strategies for achieving social influence (Archer 1988). This disadvantage can be compounded by sociocultural factors limiting female political participation (Rosaldo 1974). However, a close review of experimental literature and social systems in small-scale society reveals that women do utilize dominance-based strategies for achieving positions of social influence in ways distinct from males incorporating a dimension of prosociality (Buss 1981), oftentimes with an ontogenic component.

Women's Prosocial Dominance in Childhood

Traditional perspectives in developmental psychology have portrayed young girls as lacking expressions of dominance and overt aggression. Buss (1981) revealed the shortsightedness of these long-standing gender stereotypes demonstrating, among a sample of Western undergraduates, women tend to express social dominance in the context of group-focused behaviors, such as conflict resolution, social networking, and organization in collective action. Women are more likely to achieve positions of social influence through prosocial behavior than men, and less likely to use overt, direct aggression to subordinate followers. However, when aggression is operationalized more broadly, incorporating indirect aggression and gossip, the female dimension of social competition expands (Hess et al. 2010). In studies of Western preschoolers, Hawley has found that children most effective at controlling group resources often employ strategies of both dominance and prosociality. When the opportunity for both dominance-based and more prosocial tactics are available, there is less gender bias in social control, and group members rate boys and girls as equally as effective and desirable leaders (Hawley et al. 2008). Women use dominance-based strategies for achieving social influence in ways distinct from men, linked to their sex-specific life history parameters.

Theoretical Perspectives on Women's Expressions of Dominance

Across much of human history, and in contemporary natural fertility populations, the lives of women heavily revolved around reproduction and childcare. This has led a number of scholars to overlook and discount female-specific expressions of dominance and status competition. Several biological and psychological theories have been suggested to universally account for gender differences in the relative levels of ascribed and achieved statuses and expressions of dominance (Rosaldo 1974). The physical dominance of males over females, and the biological constraints and

parental obligations related to motherhood, are frequently cited explanations for the limited political and broader social influence of females in traditional societies. Furthermore, gender differences in socialization have been used in an attempt to explain women's confinement to the domestic sphere and disinterest in dominance-based social strategies (Rosaldo 1974).

Previous attempts to predict female's social status relative to males based on variation in societal level economics or subsistence strategies have neglected to holistically examine female-specific expressions of dominance and there are few existing theories on the subject. Some researchers assert that women are often primarily limited to domestic participation because of their maternal roles, and that extra-domestic participation by women is largely constrained because of the responsibilities related to childcare and socialization (Rosaldo 1974). This perspective suggests that because women are absorbed in household activities and direct their attention and energy toward their children, the avenues available for women to pursue dominance-based social positions and gain prestige will be shaped by their involvement in the domestic domain (Rosaldo 1974).

Heavy restriction within the domestic domain however does not exclude women from competition and expressions of dominance. Within local communities, competition between females is likely to be indirect and focused on the acquisition of valuable resources rather than political status attainment (Campbell 1999). Through indirect aggression and prosocial investments, women are able to compete socially and politically without experiencing significant risks of bodily harm (Campbell 1999). Women's high parental and reproductive investments prioritize bodily integrity and resource acquisition, over physical competition and injury (Campbell 1999). Many female psychological processes revolve around reproductive success and maternal demands. The loss of a mother can be life-threatening for young children, and natural selection has driven women to avoid physical harm in status competition in favor of a more maternal focus on current and future offspring (Campbell 1999).

In addition to an inherent aversion to physical harm, Brown (1970) suggests that the division of labor and the local political structure in traditional societies is similarly shaped by maternal demands. The subsistence activities of women are more likely to be those that are more compatible with childcare (Brown 1970). Such qualities include tasks that are located within close proximity to home, not especially cognitively demanding, and are relatively safe. Additionally, women's work will more likely be compatible with frequent interruptions from needy children (Brown 1970). While these activities prioritize successful parenting, they also serve to restrict women's ability to play a larger and more active role in local politics, at least while women are in their childrearing years.

Prosocial Expressions Through Cooperative Breeding

Other theoretical perspectives suggest that female status striving and intrasexual expressions of dominance revolve around various activities directly related to motherhood (Barkow 1989). Barkow (1989) suggests that, because in small-scale societies opportunities for expressions of dominance are often limited and infant and child mortality are typically high, a female's primary social identity may be frequently associated with her reproductive capacity and childrearing abilities. Hewlett (1991) provides comparative data from 57 traditional societies illustrating that among preindustrial populations, active hunter-gatherers suffer the greatest infant and child mortality rates with means of 23.1 and 45.5%, respectively. The combined mean data on infant and child mortality from horticulturalists and pastoralists is 21 and 38.1%, respectively (Hewlett 1991). Demographic factors, ecological pressures, and limited health care all impact female reproductive health and group-wide mortality rates. In this context, motherhood becomes a severely critical role. Women that compete for status through motherhood build reputations and gain esteem and in spheres that are valued by women and not through the activities that are necessarily valued by men.

As cooperative breeders, women in traditional societies are able to enhance their reputation and social position through their personal skills as mothers and the degree to which they participate in prosocial communal childrearing.

Post-Reproductive Prosocial Dominance Expressions

Another distinct aspect of female status striving that has been described by researchers is related to postmenopausal changes and the increased availability of status opportunities, prosocial investments, and wider political roles. Brown (1985) outlines three reasons for women's middle age status mobility. First, the end of their reproductive careers provides women in many traditional societies increased freedom from culturally specific restrictions (e.g., menstrual customs) and the constraints of childcare, giving them the opportunity to maximize their social influence and enjoy greater mobility (Brown 1985). Next, middle age grants a woman administrative authority over her juniors; she has the right to delegate tasks and organize the labor of her younger family members and also exercise great influence in important matters concerning youths' eligibility for initiation and marriage. Lastly, Brown (1985) concludes that middle age provides women with avenues for extra-domestic recognition, through the pursuit of special status positions such as curer, midwife, or ceremonial leader. Status competition and prosocial expressions of dominance in cooperative breeding yield dividends later in life when high-status women emerge as major political agents in many small-scale societies.

Conclusion

Across the life span, women are adjusting their individual strategies for pursuing positions of social influence. Women tend to use prosocial investments and communally focused behavior to increase their social rank and attain positions of influence within the group. A female-specific approach to understanding expressions of

dominance must take into account sexual selection, life history parameters, and the physiological demands of motherhood and childcare, all of which have influenced the evolved psychology of women and the cultural systems in which they operate. A broader conception of women's expressions of dominance is realized when these sex-specific features are not viewed as limitations but rather the context in which female specific social strategies have evolved.

Women's Use of Direct Versus Disguised Social Aggression

Joyce F. Benenson
Emmanuel College, Boston, MA, USA

[Indirect aggression](#); [Physical and verbal aggression](#)

Definition

Forms of social aggression.

Introduction

From an evolutionary perspective, aggression against a competitor constitutes an adaptive response to an obstacle that threatens an animal's survival and reproductive success. Because females generally engage in less direct, intense, and overt aggressive behavior than males (Archer 2004), and variance in reproductive success is lower for females (Trivers 1972), researchers often conclude that females confront fewer obstacles than males to survival and reproductive success.

Reproductive success, however, poses differing challenges for female versus male mammals. Protection of internal reproductive organs; reduction of stressors prior to conception and during

gestation; adequate nourishment during lactation; and provision of safety, nourishment, and educational and socialization opportunities to offspring define females' reproductive success in unique ways. Further, in many primate species, females' investment extends to younger siblings, offsprings' progeny, more distant kin and even non-kin helpers, whereas males invest relatively less in kin. Finally, females' impact on their own reproductive success often occurs continuously throughout their lifetimes, while males' investment occurs sporadically.

In the past two decades, research has begun to focus on the unique challenges that nonhuman and human females confront that often can be solved most efficiently by besting competitors (Clutton-Brock 2009). In addition, alternate forms of aggression, which appear better adapted to females' life histories, have been identified that are less readily observable than the salient direct displays of aggression and weaponry more frequently employed by males (Björkqvist 1994). The fact that females do benefit from aggressive behavior and that less overt forms of aggression exist, however, have illuminated facets of females' lives that have heretofore been neglected by both evolutionary biologists who study non-human animals and psychologists who study humans.

Unique Aspects of Human Females' Lives: Staying Healthy, Finding Assistants

From an evolutionary perspective, investigation of females' aggression should be directed towards understanding the unique challenges that females confront in terms of enhancing their probability of survival, procreation, and their offsprings' survival. For female mammals including humans, the initial constraint is that each female is born with all the ova she will have in her lifetime (Trivers 1972). Damage to these ova and the processes that lead to conception will produce infertility. Often neglected is the additional fact that in higher primates including humans, in natural environments offspring mortality hovers around

50 % (Volk and Atkinson 2013). A mother then implicitly and explicitly must weigh her investment in each offspring with the implicit knowledge that each has a 50 % chance of dying.

Further, human females' offspring are dependent for a longer interval than those of other species (Lancaster and Lancaster 1983). Moreover, human mothers frequently invest over their entire lifetimes in both their offsprings' survival and reproductive success (Lahdenpera et al. 2004). Finally, and most uniquely human, the prolonged nature of human childhood combined with an unusually low inter-birth interval (Bogin 1999) means that human females typically bear responsibility for the survival of several children, and later grandchildren, simultaneously. Whereas nonhuman females bear responsibility for sequential offspring throughout their lives, each offspring becomes independent more rapidly, so that a mother's reproductive success is not dependent on continued investment in the same offspring. Therefore, even more so than other female primates, from birth onwards human females must take many more precautions than males to avoid damaging their bodies so as to maximize the probabilities that they will be healthy enough to invest in their children and grandchildren. This results in the lower risk-taking of females relative to males at every life stage (Byrnes et al. 1999).

Two specific ecological factors also influence human females' success in enhancing their survival and reproductive success. First, human females are not guaranteed that they will spend their lives near kin, with the majority of societies appearing to favor male philopatry or female dispersal from their natal families and frequent residential displacements (Alvarez 2004). While competition occurs between kin, kin also typically invest more in one another than unrelated individuals (Smuts 1995). Therefore, human females must learn to reduce external signs of competition for survival for themselves and their offspring, as they would be less tolerated by non-kin, including affines.

Second, human females typically form long-term pair bonds with the fathers of their children. The sexual division of labor means that females

often are dependent on men for specific foods, such as meat, and for other responsibilities, such as protection from other men and assistance with child care. Further, when women are pregnant or lactating, they need extra calories and are particularly vulnerable. A marital partner often provides resources that are difficult to obtain when a mother has young children, whether animal foods or other currencies (Marlowe 2005). A marital partner also provides protection from infanticide and abduction. Additionally, because human males hold higher status than females, forming a long-term bond with a man provides status and links to the community that a lone female often lacks (Rucas et al. 2012). When kin are unavailable, both husbands and affines can compensate by provisioning mothers and children and providing direct child care as well. Consequently, maintaining access to kin and the father of her children and her affines constitutes a critical means for a mother to improve her own and her children's survival and reproductive success. Maintenance of bonds to kin or to the father of her children provides such advantages to raising simultaneously dependent children and bearing lifelong responsibility for them that when these bonds are threatened, the benefits of aggression utilized to restore the bonds may outweigh the costs.

To stay alive, all females require safety, food, territory, and other resources. To thrive, social females benefit from educational and socialization resources as well as status. For human females to accomplish the tasks of keeping their children alive and helping them to thrive, they need assistants. Most of these assistants are kin or husbands and affines. Because unrelated females share the same goals, they become competitors for scarce resources or allies or mates. Consequently, it is unrelated females who constitute typical targets of aggression.

Forms of Individual Aggression

Direct physical aggression. The primary advantage of direct physical aggression is its rapid occurrence which is essential to stopping a

predator or a strange male who threaten a female's or her children's survival. Although this immediate response is critical when the target is determined to attack, in more ambiguous cases such as abductions by males or attacks by female competitors, the rapidity means the target has little chance to escape or debate whether to retaliate. This may increase the probability that the target retaliates physically either for defensive purposes or as an offensive counter-attack, leading to severe physical injury.

As an offensive strategy, the rapidity and surprise of direct physical aggression can overwhelm the target, potentially increasing the probability of success. However, a direct physical attack has the potential to severely injure the perpetrator as well as the target, particularly when the target is equal in size and strength to the perpetrator. For this reason, even males typically utilize bluffs before actually physically fighting (Maynard Smith and Price 1973).

Even if direct physical aggression does not injure the perpetrator, it is costly in terms of expenditures of physical and emotional energy. Only when a coalition cooperates against a target can the risks of retaliation and energy expenditure be reduced, but this requires planning and inflicts large opportunity costs, which mothers of dependent children rarely can bear.

An additional disadvantage of a direct physical attack is that the perpetrator typically is unable to disguise her identity. Even if retaliation does not occur immediately, future retaliation by the victim, and his or her allies, arises as a future and omnipresent threat.

To avoid injury to their ova, reproductive organs, and their ability to survive to care for their children and grandchildren, human females therefore must reduce the probability of injury and death (Campbell 1999). Accordingly, from early in childhood (Maccoby and Jacklin 1974) through adulthood (Archer 2004) human females utilize direct aggression much less than males do. This fact alone can help explain why across species males' direct aggression has been the focus of investigation more than females' aggression. Although other forms of aggression take longer to be effective, they are safer and hence more

widely utilized by females. Only when a female's survival or reproductive success is in immediate jeopardy should she resort to direct physical aggression.

Direct verbal aggression. Verbal aggression is not as effective as direct physical aggression at attaining an immediate goal. Although it can be executed rapidly, it does not interfere to the same extent with the obstacles created by a target. Nonetheless, the emotional impact, particularly when accompanied by the threat of physical aggression, can be valuable in thwarting a target. Direct verbal aggression also has the advantage of not requiring a response from the target, thereby further reducing threats to the perpetrator's safety. Additionally, because direct verbal aggression requires fewer physical and emotional resources, it can be utilized for longer intervals than direct physical aggression.

Direct verbal aggression provides a further advantage through its explicit communication of negative information to a target. Understanding the perpetrator's perspective allows the target to determine whether it is worth modifying personal goals to maintain harmony with the perpetrator. This should theoretically also permit the possibility of later reconciliation. Direct verbal aggression also can be utilized to publicly disseminate negative information about a target, thereby impugning a target's reputation. With a crowd present, the perpetrator's chances of a retaliatory physical response from the target are reduced.

Therefore, whereas physical aggression has the advantage of producing the desired outcome most rapidly, verbal aggression provides several advantages, including conveying precise negative information to and about the target, while reducing the probability of injury.

A major disadvantage of direct verbal aggression, however, is that similar to physical aggression, the perpetrator typically cannot disguise her identity. Consequently, immediate or delayed physical or verbal retaliation by the target is more probable than when the perpetrator's identity is concealed.

Disguised physical, verbal, and nonverbal aggression. Concealing one's identity produces large advantages for a female aggressor who

must reduce her own and her progeny's probability of physical retaliation (Björkqvist 1994). A variety of means exist for disguising direct physical aggression. Identity can be masked through covering the face and body and through the anonymity afforded by large coalitions, but this type of disguised physical aggression still risks physical injury to the perpetrator. No evidence therefore indicates that human females commonly utilize this type of disguised physical aggression.

In contrast, females do utilize another form of disguised physical aggression: aggressing against another's property or allies in her absence. This type of disguised physical aggression includes stealing food or the means for the production of food, destroying a shelter or clothing, or even poisoning a child (Burbank 1987). The probability of physical injury and future retaliation is reduced due to the target's absence. Nonetheless, because it leaves physical traces, the perpetrator's identity potentially still can be discovered, enhancing the potential for retaliation. The extent to which females employ this type of disguised aggression has not been studied.

In contrast, across diverse cultures, females utilize disguised verbal aggression regularly, although there is no evidence that they utilize it more frequently than males do (Archer and Coyne 2005). Rather because females employ less direct forms of aggression, disguised forms of aggression constitute a larger proportion of females' aggression. Disguised forms of aggression therefore have become associated with females, even though males utilize them as much or more.

The first form of disguised verbal aggression, verbal denigration of an absent target, also termed gossip, can produce severe reputational damage to a target, leading the target's erstwhile allies, including friends and mates, to reduce their investment or even to sever their connections with the target all together. Absent a written form, no concrete evidence may exist as to the identity of the perpetrator. The perpetrator, however, must discourage listeners from divulging her identity. If the perpetrator's identity is revealed however, she always can either deny malevolence or attribute malicious intentions to the

messengers. In modern cultures, females can engage in disguised verbal aggression through online forums. Again, however, there is no evidence that females engage in more online incidences of disguised verbal aggression than males do (Tokunaga 2010).

Another form of disguised verbal aggression can occur in the target's presence if the words, tone of voice, cadence, or other auditory signals contain enough ambiguity to confuse the target. As one example, public expressions of purported concern towards a target, including direct and ostensibly sincere questions about a target's comportment and feelings, can have the effect of exposing precise weaknesses of a target. Disingenuous sympathy is particularly effective for females who are expected to be nurturing and sympathetic and helps to disarm a target's defenses as the perpetrator can falsely claim to be invested in the target's well-being. Likewise, pitying tones of voice, clucking noises, and giggling can be employed to convey derogatory evaluations of a target with enough ambiguity to preclude clear interpretation by the target. In the presence of others, denigration of the target's character reduces the bonds between the target and her allies, including friends and mates, thereby permitting the perpetrator to steal allies and/or reduce the target's support in the community.

Even nonverbal derogatory gestures, if they are subtle and hence ambiguous enough, can be utilized to aggress against a target in her presence. These include awkward pauses, twisted facial features, belligerent head or eye movements, or propulsive actions with fingers, arms, legs, or other bodily parts, again with the purpose of publicly denigrating the target, and disrupting the target's social connections. These types of aggressive gestures seem particularly well-suited to females who are more sensitive than males to subtle social cues (Hall et al. 2000). Therefore, intrasexual female aggression can occur in mixed-sex settings without males' awareness. This can be useful if the goal is not to communicate the information to males, who often wish to maintain the status quo and hence would punish female aggression.

Finally, implicitly withholding benefits, whether material, social, and in the case of males, sexual, until a goal is attained, may be as effective as inflicting costs (Björkqvist 1994). This latter strategy, however, requires that the perpetrator be in a position to dispense and therefore withhold benefits. Whereas there is no evidence that human females practice any of these disguised forms of aggression more frequently than males do in absolute terms, much evidence suggests that these forms of aggression constitute a larger percentage of females' aggressive repertoires simply because females use direct physical and verbal aggression so much less frequently than males do.

Two forms of aggression, however, do appear to be utilized by females more than males: Insistence on the maintenance of equality and social exclusion. Insistence on the maintenance of equality with other females (Maltz et al. 1982) effectively reduces same-sex competitors' advantages. Unlike males who from early childhood through adulthood directly compete physically and verbally for resources, allies, and status, females actively pursue a very different strategy: No female is allowed to claim superiority to any other female. Beginning in early childhood, girls and women rapidly disparage any female who exhibits material or social advantages or claims superior performance. The disparagement occurs both in the absence and presence of the target. While ostensibly sounding positive by purporting to denigrate competitive motives, unequal outcomes, and hierarchical social structures, the perpetrator utilizes this form of disguised aggression to force competitors to surrender time, resources, and positions of status. Furthermore, joint insistence on equality can lead to social exclusion of an advantaged target. Consequently, any female striving to attain her goals must disguise her pursuits by focusing on her deficiencies and dearth of accomplishments. This retaliatory strategy cannot be easily discerned as it fits within the stereotype of the self-effacing female, but it poses risks to any female whose advantages are revealed despite her attempts to disguise them.

Social exclusion constitutes the second form of uniquely female strategy. The study of aggression

typically is divided into individual versus coalitionary forms, and social exclusion is coalitionary.

Forms of Coalitionary Aggression

Social exclusion. By definition, social exclusion requires a coalition of individuals who outnumber their victims. The most commonly documented form of social exclusion occurs when a coalition of females gangs up on an individual female and attempts to sever her connections to the larger community. Whereas evidence suggests that social exclusion is equally painful for both sexes, it appears that females utilize it more frequently (Benenson et al. 2013).

Social exclusion initially can occur through disguised means, but eventually it must become direct. A coalition chooses its target, typically someone who is either unconnected to others and hence easily ousted, or someone whose ouster will free up time, energy, resources, territory, connections, or a position of status for the remaining female members of the community.

Because of the imbalance of power, social exclusion is extremely safe. Thus, it may be the preferred mode of aggression for females who benefit greatly from avoiding injury. Even at its most direct, a victim cannot retaliate immediately or at a later time, unless the victim finds her own coalitionary partners. It is unlikely, however, for a lone target to find allies after the process of social exclusion is underway, as potential allies would risk subjecting themselves to the same treatment, with little obvious benefit. The ultimate goal of social exclusion is to force the target to leave the community.

Similar to the female norm of equality which facilitates the insistence that no other female demonstrate advantages, social exclusion appears particularly well-suited to female competitors because females do not benefit as much as males do from cooperation with unrelated same-sex peers. Since a human mother experiences difficulty raising her children on her own, she benefits greatly from assistance in procuring resources, minding children, and educating and socializing

them. The assistants cannot be other mothers, however. By definition, a mother typically does not have additional time, energy, resources, or allies they can provide to another mother without jeopardizing their own and their children's survival and reproductive success. Consequently, kin, husbands, and affines constitute the most useful assistants.

Thus, unrelated women compete for themselves and their children for the same resources and allies, including a husband who invests in her and her children. Maintaining a long-term pair bond with the father of her children requires that a mother ensures that other females do not disrupt the relationship. For all of these reasons, reducing the number of female competitors benefits a female at any stage of her life. Social exclusion therefore constitutes a highly effective strategy from early childhood throughout adulthood for reducing the number of competitors.

Bullying. Bullying is similar to social exclusion insofar as several individuals gang up on a vulnerable, lone individual (Olweus 1993). However, there is no attempt to ostracize the individual. Rather, bullying seems to operate as a means of maintaining a coalition and perhaps providing status for the lead instigators. Should the victim disappear, the coalition as well as the status of the primary perpetrators may disappear. Paradoxically, therefore, the intent seems to be for the victim to remain part of the community.

Both bullying and cyberbullying (Tokunaga 2010) are more commonly utilized by males than females. For both sexes however, bullying is directed by higher-status individuals towards lower-status individuals. Lower-status boys, however, will bully higher-status girls (Olweus 1993).

Intergroup aggression. Because human males more than females interact in groups, intergroup aggression is practiced primarily by males from early in life. Whereas both sexes prefer their own groups over other groups (Tajfel 1981), females typically do not engage in aggression against out-groups. Intercommunity aggression in its most extreme form, warfare, rarely involves females playing primary roles. Lack of cooperation in warfare and other group enterprises with unrelated same-sex peers means that power

is not derived from greater numbers. Consequently, social exclusion is more useful as an aggressive strategy for females than males.

Prioritizing Aggressive Strategies of Females

Selection of the form of aggression depends on the goals of the perpetrator. For females who are born with a finite number of ova; who beginning in adolescence experience fluctuating hormonal levels that must be finely balanced to permit conception; whose reproductive organs must be healthy enough to allow years of internal gestation; whose children require her investment to survive; and finally whose grandchildren will experience lower mortality and morbidity if she can invest in them potential injury must be minimized.

The first principle of female aggression therefore is to reduce the chance of injury and death (Campbell 1999). Direct physical aggression therefore should be utilized primarily to enhance survival and otherwise avoided. Direct verbal aggression should follow as the second least preferred form of aggression as the potential for retaliation is higher than when forms of aggression are disguised. It seems highly probable that both direct physical and verbal aggression are utilized only when the likelihood of retaliation is minimal, such as against targets who are physically weak and socially unconnected or with individuals who will not retaliate. Children or low-status and physically weak non-kin and kin would constitute the safest targets. However, where strict laws exist to protect women, females would be more likely to employ direct physical and verbal aggression against kin and spouses and others of similar or greater physical strength (Archer 2000).

Insistence on maintenance of equality likely constitutes the least dangerous form of aggression and hence should be the most common strategy. Requiring another female who is in an advantageous position to relinquish her lead for the sake of equality cleverly disguises competitive goals and invites no retaliation. This insistence can

occur directly and by a single perpetrator because the risk of retaliation is so minimal. Joint insistence, however, can lead to the second most effective female strategy: Social exclusion. Because of the protection that a coalition provides against a lone victim who cannot easily retaliate, social exclusion is safe and provides numerous benefits, particularly reducing competition over mates.

In between the most and least dangerous forms of aggression are disguised forms of aggression that are not costly, including verbal denigration in the target's absence and subtle forms of verbal and nonverbal denigration in the target's presence. This latter type of subtle aggression most likely is more effectively utilized by females than males who are less skilled in decoding the nuances of verbal and nonverbal communication. For females, these subtle forms of aggression can permit "doublespeak" whereby a female can be recorded explicitly as supporting someone, but the implicitly negative message supersedes the explicit message at least amongst her female interlocutors.

Sex Differences in Aggression

Mammalian males typically directly compete for access to females, then to attract females. Although the variance in reproductive success is greater for males than females, individual females differ markedly in their survival and that of their grandchildren. In humans although both sexes invest to some extent in children, females universally bear primary responsibility for child care.

Rather than competing for sexual access therefore, females compete for long-term relationships to individuals who will invest in her children and who will directly compete for status. Finding valuable assistants is critical to females. This goal is complicated by human male philopatry and hence females' concomitant frequent lack of connections to kin. Consequently, those women who can attract and keep a husband who provides resources, protection, status, and links to the community greatly enhance their probabilities of their survival and

reproductive success over their lifetimes (Rucas et al. 2012). Those women who can maintain access to and investment from their own kin similarly benefit. Because cross-culturally women typically begin bearing children before they turn 20 years, a woman who can maintain strong connections with kin and form a long-term bond with a mate by the end of adolescence can best ensure her own and her children's survival and status. Maintenance of these bonds, or formation of sequential long-term bonds with the fathers of her children along with continual renewal of ties with kin as occurs in hunter-gatherer communities, greatly benefit a mother's survival and reproductive success.

During childhood and particularly adolescence therefore, in monogamous communities, unrelated same-sex individuals may be friendly but they also constitute competitors for mates. This continues into adulthood especially in communities in which divorce is commonly practiced. In communities that practice polygyny, those females who share the same mate likewise benefit when there are fewer co-wives with whom to share resources as well as a husband's time, energy, and emotional commitment. Social exclusion, particularly of attractive females, therefore provides a safe and highly beneficial strategy for reducing the competition.

Nonetheless, unrelated same-sex peers can provide human females with emotional support and information, coalitions to exclude other females, and friendships that reduce the probability of being excluded by other females. They can also provide assistance with joint goals, such as building shelters, locating food sources, and providing information about others in the community. Further, mothers benefit from mutually permitting their children to educate and entertain one another. Nevertheless, mothers' high investment in their own children and need for external assistance likely preclude the type of sharing of time, resources, energy, and status that more typically characterize the relationships between unrelated men (Hawkes et al. 1997). Aggressive strategies therefore are most likely to be deployed by human females against unrelated same-sex women, despite their sharing common goals.

Conclusion

Women's choice of differing forms of social aggression depends on females' unique obstacles to survival and reproductive success. The most important reason that females and males differ in their forms of aggressive strategies is that females have more to lose in terms of reproductive success from sustaining physical injuries. Consequently, selecting aggressive strategies that minimize the chance of retaliation reduces the cost:benefit ratio to females of employing aggression.

Synonyms

Dual-mechanism morphology; Dual-route model

Definition

“Words and rules” postulates a dual mechanism of symbolic rules and associative storage and retrieval for the production and comprehension of morphologically complex words.

Introduction

It has been suggested that the access and production of morphologically complex forms can occur via two routes (Pinker and Prince 1994). First, a morphologically complex word can be listed in the mental lexicon as a whole form and produced or

comprehended by direct lookup (“words”) or alternatively, a decompositional route may be used where the complex form is parsed into a stem and a symbolic rule that applies to all stems of that category to create the complex form (“rules”). But there are also competing theoretical viewpoints that suggest that *single-route models* that rely solely on associative memory (Rumelhart and McClelland 1986) could also successfully reflect human performance with morphologically complex forms. This research will be laid out under three main headings: (1) inflectional morphology and child language acquisition, (2) crosslinguistic data, and (3) challenges for the words and rules model.

The English Past Tense: The First Battleground for Single- and Dual-Route Models

The production and processing of the past tense forms of English verbs has often served as a testing ground for the hypotheses of two competing accounts regarding the organization of language in the human mind, with particular attention devoted to children's overregularization errors (e.g. *throwed*, instead of *threw*). On one side of this debate, one finds the proponents of the *single-route models* who suggest that *all* morphologically complex forms are stored in the memory as chunks and that the production of new complex forms depends on the analogization of memorized (sub)regularities, e.g., *pump* → *pumped* can be derived by analogy to *jump* → *jumped* via associative links established between their phonological features, just as *throw* → *threw* can be derived by analogy to *know* → *knew* (Rumelhart and McClelland 1986; Plunkett and Marchman 1991, 1993). On this view the overregularized form *throwed* could be claimed to occur because of existing regular forms that are similar to it, such as *glowed*. On the other side of the debate are the proponents of the *dual-route models* (aka “words and rules”) who claim that while the past tense forms of irregular verbs such as *threw* or *knew* are stored in memory and can be derived by analogy, the past tense forms of regular verbs such as *pumped* must be derived by a

symbolic concatenation rule ($V + ed$), regardless of the phonological similarity of the stem to existing regular forms (Prasada and Pinker 1993). The existence of overregularized forms would then be explained by a failure to retrieve the stored irregular form, which leads to the default application of the rule (Pinker and Prince 1988; Marcus et al. 1992). Research on the psychological validity of “the words and rules model” and its role in language development will be presented under the following headings: (1) inflectional morphology and child language acquisition, (2) crosslinguistic data, and (3) challenges for the words and rules model.

Inflectional Morphology and Child Language Acquisition

Inflectional morphemes encode grammatical features such as tense, number, and gender. Research has shown that, once children have acquired a rule of inflection, they are willing to apply it to novel cases, generating the plural forms of made-up nouns (e.g., /wag/ → /wagz/) or the past tense forms of made-up verbs (e.g., /biŋ/ → /biŋd/). As the stems *wug* and *bing* are not real English words, the child who correctly inflects them shows evidence of having acquired the inflectional rules and of using them productively (Berko 1958). One puzzling finding, however, has been that English-speaking children do not smoothly enter an adult-like stage where they use regularly and irregularly inflected words equally proficiently. Instead, they appear to exhibit a pattern of *U-shaped development*, whereby a period of relatively error-free performance is followed by a period in which children overapply the regular rule to irregulars (e.g. *throw* → *throwed*) and then converge on adult performance over time (Cazden 1968).

It has been suggested that the emergence of these overregularization errors is attributable to a change in children’s vocabulary, i.e., children would be first exposed to a restricted class of high-frequency irregulars in the parental speech the past tense forms of which they retain in memory, but over time the regulars would come to

outnumber the irregulars, dominating children’s vocabulary and prompting them to overregularize. This fundamental assumption about the changes in a child’s vocabulary is true for the *type frequency* of verbs. The irregular verb vocabulary of an English-speaking child will expand as he/she is learning the modest number (~180) of irregular English verbs and then it will plateau. The regular verb vocabulary will, however, grow continuously; as the regular verbs form an open class. Yet the high type frequency of regular verbs in the child’s vocabulary is not found to be positively correlated with the overregularization rate, so it cannot be argued that this quantitative change in the vocabulary is the cause of the overregularization errors. An alternative approach could be to take *token frequencies* into account, rather than type frequencies. But irregular verbs have, in fact, a higher token frequency, so this does not explain the overregularization errors either (Marcus et al. 1992).

The words and rules model, in contrast, explains overregularization errors with the *blocking-and-retrieval failure hypothesis* (Marcus et al. 1992; Ullman 1993). This hypothesis states that the language system depends on two separate but interacting components: a computational component for symbol manipulation and an associative component for analogy-based storage and retrieval. In this system, rules constitute the default mechanism by which morphologically complex forms are generated, and they always apply as long as they are not *blocked* from applying by a specific irregular form retrieved from memory. This dual mechanism naturally predicts that children will overregularize, since they have not heard some irregular verbs as often enough to consolidate their traces in memory, and in the absence of the irregular past tense form that would block the rule; the rule applies. Thus overregularization errors are a direct consequence of having a rule and a built-in blocking principle at one’s disposal. Moreover, as the blocking principle is quite robust and the memory retrieval process often works, it is expected that overregularization errors should be relatively rare, and this prediction appears to be borne out in child language corpora collected in naturalistic settings

(Marcus et al. 1992); however, see Maratsos (1993, 2000) for a different point of view. Additional evidence showing that children are aware of the inflectional rules and the environments that license their use is supplied by children's preference for irregular plurals over regular plurals in the non-head positions of compounds where an item drawn from the mental lexicon would be permitted (e.g., mice-infested), but not a regularly inflected form which is the output of a later morphological operation than compounding (e.g., *rats-infested, where * shows the ungrammaticality of the structure, in accordance with the linguistic conventions) (Kiparsky 1982; Gordon 1985) and by children's reluctance to regularly inflect headless compounds where the irregularity of the root cannot percolate up to the whole derivation (*sabertooths*, not **saberteeth*) and denominal verbs (*flied the board*, not **flew the board*, where *to fly* means *to cover a surface with flies*) where the canonical verb root is not available to activate the irregular past tense form (Kim et al. 1994). These findings provide evidence for the bifurcation of the language system into an associative memory component and a rule-based computational component in English-speaking children's minds.

Crosslinguistic Data

Though psycholinguistic research on the words and rules model tended to focus on English past tense morphology, some evidence in its favor has also been adduced in studies on other languages both with adults and child speakers. Experiments conducted on Hebrew-speaking adults have shown that the regular masculine plural form is freely overapplied to novel nouns, borrowings, and names, irrespective of their phonological similarity to existing forms, unlike the irregular-sounding forms which were sensitive to phonological similarity with the stored forms (Berent et al. 1999).

Studies on German concentrated on the formation of past participles and plurals. In German, the most common participle ending is $\{-t\}$, which is attached to verb stems (e.g., *kauf-en*, "to buy" →

ge-kauf-t, "bought") in a regular fashion. Another participle ending, $\{-n\}$, however, is less common and often accompanied by stem changes (e.g., *schreib-en*, "to write" → *ge-schrieb-en*, "written"), forming a parallel to the irregular past tense forms in English. In line with the predictions of the words and rules model, Marcus et al. (1995) have found that adults predominantly generalize the $\{-t\}$ ending to the participle forms of denominal verbs that lack a canonical root, whereas the irregular $\{-n\}$ ending is used for homophonous verbs derived from a verb root that would normally be inflected with $\{-n\}$. Other studies confirmed these findings with both adults and children. As expected, no clear similarity effects were found for the overregularization errors (see Clahsen 1997). But these results could also be compatible with *single-route models*, since the default status of the participle ending $\{-t\}$ is confounded with its status as the most frequent participle ending and as it is known that high-type frequency leads to the extraction of a default pattern in associative networks employed by single-route models. The words and rules model, however, contends that there is no link between the *descriptively* default status of an inflection (i.e., its type frequency) and its *psychologically* default status (i.e., its generalizability in circumstances where no stored form is available). Thus an inflectional form that dissociates between these two confounded criteria, a *minority default*, is needed to confirm that such overregularization errors constitute an argument for the dual-route models.

The German plural ending $\{-s\}$ is claimed to be an appropriate candidate in this respect. According to different corpus-based estimates, its frequency varies between 0 and 9%, yet it is the *psychologically* default plural suffix (Marcus et al. 1995), as judged by its use for loanwords, quotations, acronyms, and similar environments where a canonical root would be absent and irregular inflection blocked. The default status of $\{-s\}$ for adults has found support in an experiment where the participants had to judge the "well-formedness" of pluralized novel words. The results showed that particularly novel names that did not rhyme with existing irregular nouns were found to sound better when pluralized with $\{-s\}$

(Marcus et al. 1995). Based on longitudinal data from one child acquiring German, Clahsen et al. (1992) also suggest that $\{-s\}$ was the most frequent suffix in overregularization errors and was missing from the non-head positions in compounds where regularly inflected forms would not be allowed. Moreover this child also pluralized words of her own invention with $\{-s\}$ lending support to the hypothesis that $\{-s\}$ may be the default plural marker for German. The possibility of having a default inflection that is not the most frequent inflection at the same time is cited as evidence for the words and rules model, where the default status of a symbolic process is logically independent of its type frequency. The claim that single-route models cannot accommodate minority defaults, however, has not gone unchallenged (see Hahn and Nakisa (2000) for a discussion).

Additional support for the words and rules model is provided by Spanish, where children have been reported to overextend regular verbal inflectional suffixes to irregulars, while errors in the reverse direction (irregular forms overextended to regulars) were very rare (Clahsen et al. 2002). Furthermore it has been shown that the emergence of such overregularization errors in Spanish coincides with the time when the relevant forms start being used contrastively by the child (Mueller-Gathercole et al. 1999) or with the emergence of obligatory finiteness markings (Clahsen et al. 2002), which implies that overregularization may be a direct consequence of acquiring a rule of inflection.

Drawing upon elicited production data from adults, Say and Clahsen (2002) discuss the evidence for the words and rules model in Italian novel verb past participle formation. Italian has three conjugation classes, of which the first one is predicted to be the default, since it applies to loanwords, neologisms, deadjectival and denominal verbs, and onomatopoeic verbs – popular diagnostic environments for productive patterns. The other two conjugation classes, however, are excluded from these environments. As predicted, Say and Clahsen (2002) found that adult native speakers of Italian tended to overgeneralize the first conjugation to novel verbs

that bore no similarity to existing verbs in the other two unproductive conjugation classes, thus confirming the default status of the first conjugation class in the minds of Italian speakers. In contrast, second and third conjugations were only generalized to novel verbs that were phonologically similar to existing verbs in these classes. The same study provides additional evidence for the bifurcation of regular and irregular conjugation classes by presenting ERP data. It is shown that a clear ERP effect is only found with overregularized irregulars, whereas the ERP effects triggered by incorrect regulars are negligible.

All in all, the data obtained in studies on English and other languages cited in favor of the words and rules model appear to concur on two key points: (1) regular forms are generalized freely, whereas irregular forms tend to be generalized only if the root is phonologically similar to another irregular root. (2) Generalization of irregular forms shows frequency effects, whereas generalization of regular forms does not have to be related to their frequency.

Challenges for the Words and Rules Model

The words and rules model has been very influential in the field of morphology and psycholinguistics, but criticisms of its main assumptions and their implications were quick to follow. For example, it has been noted by Yang (2002) that the blocking principle invoked by the proponents of the words and rules model to account for overregularization errors is a problematic concept when it is interpreted in an absolute sense, as it is incompatible with the presence of *doublets*, the verbs that have coexisting regular and irregular past tense forms such as *dived-dove*, *thrived-throve*, etc. If the blocking principle is operated in an absolute manner, we would have to expect the irregular past tense forms to preempt the use of the regular forms. In addition, the reliance of the words and rules model on analogy/family resemblance to explain connections between the stems and past tense forms of irregulars is criticized. First, the notion of *analogy* is argued to be too

vague and to not lend itself to operationalization and quantitative predictions. In addition, it is pointed out that analogy would only work if phonological similarity was strong *within* a class, but weak *across* classes, so a given irregular verb could be reliably paired with a certain stem change based on family resemblance to other irregular items that undergo the same stem change. But this is not the case, as there are irregular forms that are phonologically very similar to each other but nevertheless fall into different irregular classes, (e.g., *split-split*, but *spit-spat*). Furthermore, relying on the frequencies of individual irregular verbs to explain their varying susceptibility to overregularization is also problematic, since it makes it impossible to explain the so-called *free-rider* effect where an irregular verb with low input frequency (e.g. *hurt*, *cut*) is used fairly accurately in the past tense, presumably owing to the frequency of the other items in the irregular class to which it belongs (no change: *cut*, *put*, *hit*, etc.). Yang (2002) argues that a single-mechanism model that relies not on associative memory but on various rules that compete with each other (including the regular *suffixation* rule and a number of *readjustment* rules for the changes that irregulars undergo) and are accessed probabilistically can better account for these tendencies.

A further problem with the words and rules model concerns the extraction of a default pattern that speakers can fall back on when they fail to retrieve the memorized irregular form. In English past tense formation, this process seems to run smoothly, but there have been suggestions in the literature that not all languages may have a default inflection that is overgeneralized like the English {-ed} suffix. Dąbrowska (2001, 2004) points out that Polish does not have a default masculine singular genitive suffix that is uniquely overgeneralized. The two suffixes, {-a} and {-u}, can both apply to diagnostic environments of defaultness: adults productively use both suffixes with nonce words (Dąbrowska 2004), and a corpus of spontaneous speech of three Polish children indicates that the relative (i.e., proportionately to the frequency of occurrence in the children's speech) overgeneralization rates of these two

suffixes is roughly the same, so Polish children do not appear to have misconstrued one suffix as the default (Dąbrowska 2001, 2004). Interestingly, this contrasts with the performance of Polish children with respect to the genitive plurals, where the suffix {-ów} is consistently overgeneralized to forms that would require a stem change or a zero form for genitive marking, similarly to the past tense overregularizations in English. This qualitative difference between the two declensions may be related to the properties of these two inflectional subsystems, i.e., overgeneralization of one default suffix may occur when the suffix competes with a non-concatenative form as in the case of genitive plurals, but not when two or more suffixes compete with each other (e.g., masculine singular genitive). This also shows that some concomitant properties of English inflections, such as the one-to-one correspondence of stem changes to irregularity and suffixation to regularity, may be partly responsible for the neat regular/irregular distinction in English. For some languages where both irregular and regular morphologies employ concatenation or stem change, the regular/irregular distinction may not be as pronounced as it is in English, as judged by the criteria put forth by the words and rules model.

The problem of multiple defaults is not limited to Polish. Dutch has two plural suffixes, {-en} and {-s}, and {-s} is reported to be missing from the non-head positions of compounds, whereas {-en} is found in this position. By analogy to the difference between the acceptability of the forms *mice-infested* and **rats-infested* in English, one would have to conclude that {-s} should be a regular suffix in Dutch, while {-en} is irregular (Gordon 1985). But as Pinker and Prince (1994) note, both of these suffixes are applied productively by Dutch speakers in their respective domains of application, and they also appear in the diagnostic environments for regularity/defaultness, which suggests that Dutch has two default suffixes for marking plurality. Keuleers et al. (2007), on the other hand, point out that the choice of the default plural suffix depends on the phonological properties of the stem, and this finding contradicts the dual-

mechanism notion that the default rule applies regardless of the item-level phonological features of a word if it belongs to the right category. To explain this sensitivity to phonology, it should be either conceded that forms pluralized with both suffixes are stored in associative memory, or a phonologically conditioned default system must be implemented. But it turns out that a phonologically conditioned system has its own problems, since a production task shows that adult native speakers appear to supply the suffix $\{-s\}$ for pseudowords with English orthography, even when their phonology predicts $\{-en\}$. This indicates that even knowing the rules of a foreign language can have an effect on speakers' choices of inflection for a loanword. Therefore it has been argued that the Dutch plural inflection can best be handled by a *single-route model* that is allowed to exploit different information sources for establishing analogies (Keuleers et al. 2007).

The German data showing the preferred use of $\{-s\}$ in the absence of canonical roots and its involvement in overregularization errors were interpreted as a sign that $\{-s\}$ is the regular default plural suffix despite its infrequency (Clahsen et al. 1992; Marcus et al. 1995). But this conclusion appears flawed under close scrutiny. Later studies on the acquisition of German plurals have provided evidence that children overgeneralize $\{-(e)n\}$ at least as often as $\{-s\}$ (Szagun 2001), if not more often (Bittner and Köpcke 2000). Moreover, Szagun (2001) emphasizes that the environments where $\{-s\}$ is overgeneralized show that the overgeneralization errors are not related to the putative default status of $\{-s\}$, but to a phonologically conditioned analogization process. In adult German, $\{-s\}$ usually appears with words that end in an unstressed vowel such as *Uhu-s* ('eagle owls'). Interestingly, children in Szagun's study incorrectly overapplied $\{-s\}$ mostly to nouns that end in an orthographic *-er* pronounced as [ɐ] (e.g. **tiger-s*, **jäger-s*), suggesting that the errors are sensitive to the phonological regularities of the environments where different plural markers occur. The preponderance of $\{-(e)n\}$ overgeneralizations can also be accounted for without invoking a default rule. The plural suffix $\{-(e)n\}$ has high cue strength as measured by its perceptual saliency (i.e., it creates a new syllable), cue validity (i.e., it is a reliable cue for signaling plurality), and type frequency (i.e., it facilitates pattern extraction). In a schema-learning model (Bybee and Slobin 1982), these factors can lead the child to form a schema with $\{-(e)n\}$ and to overapply it, as it is the *best exemplar* for forming the plural in German (Köpcke 1998; Bittner and Köpcke 2000).

These findings show that the words and rules model needs to accommodate divergent crosslinguistic data, such as multiple default inflections as in Polish and Dutch and the sensitivity of regular patterns to phonological properties and type frequency as in Dutch and German. As a matter of fact, the effect of phonological properties on regular inflection is not limited to languages other than English. In English, too, research indicates that overregularization errors are predicted by not only the infrequency of the irregular stem, but also by its phonological resemblance to frequent regular items (Marchman and Callan 1995; Marchman 1997). For example, the verb *throw*, which has many regular *enemies* such as *mow*, *plow*, and *glow*, is predicted (and shown) to be more prone to overregularization than *hit*, which has a smaller number of regular *enemies*. This is presented as evidence for the claim that associative memory can and should be involved in the production of regular forms. Though they do not endorse the single-route models, Albright and Hayes (2003) follow Marchman and colleagues in rejecting the dual-mechanism idea that regular stems, unlike irregulars, cannot form phonologically based clusters that attract the regular inflection (Pinker and Prince 1988; Prasada and Pinker 1993) and note that regular verbs in English (as well as irregulars) fall into *islands of reliability*, where a rule is said to apply even more reliably. Reliability is operationalized as the ratio of the *hits* of a rule in a context (i.e., how many stems are inflected with that rule) to the *scope* of the rule (i.e., how many stems fit the structural description of the rule). Thus the rule that adds a $[-t]$ suffix (the allomorph of the English past tense suffix for verb stems that end in a voiceless consonant) after verb stems that end in voiceless fricatives

will have a reliability score of 1, because all English verbs ending in a voiceless fricative happen to be regular. Albright and Hayes (2003) created a model that generates multiple stochastic rules with different well-formedness/reliability values and that chooses the most reliable rule to derive the output of a morphological operation. They found that the model's output largely reflected native speakers' acceptability judgments for and productions of the past tense forms of novel verbs. In contrast to the predictions of dual-route models, this effect was robust for both regulars and irregulars. Similar results have been obtained with Italian verbal inflections (Albright 2002). This shows that speakers can extract sub-regularities based on the phonological shape of the stems and can choose the best exemplar among a number of rules to apply to a given stem. While this line of reasoning is strongly reminiscent of the schema theory with its emphasis on best exemplars and type frequency (Bybee and Slobin 1982; Bybee 1995), it differs from it by giving precedence to multiple rules over analogization (Albright and Hayes 2003). Yet it is clear that dual-route models will have to either allow more stored regular forms or a larger number of rules in the grammar in order to accommodate the gradient well-formedness of rules in different phonological environments (Albright 2002; Yang 2002).

Conclusion

The "words and rules" model has been very influential particularly in the 1980s and 1990s and has motivated extensive research into the psychological validity of morphological rules. While a plethora of evidence has been accumulated in favor of this model, later studies have shown many of its basic assumptions to be neither necessary nor sufficient to justify a dual-mechanism morphology and provided data incompatible with its predictions. That being said, the jury is still out on the question of whether a single-route model or a dual-route model can better approximate human performance with regularly and irregularly inflected words. To better characterize the

cognitive architecture that subserves the processing of morphologically complex words, future studies should focus on working out more precise hypotheses and on garnering data from a wider range of languages with different inflectional systems.

Definition

A cognitive system responsible for storing and manipulating information, for a short time period, for the completion of an action, such as a mathematical problem (mental action) or following the correct process on a recipe you just heard (physical action).

Introduction

Working memory, an evidence supported theoretical construct, is defined as the cognitive system responsible for storing and manipulating information, for a short time period, for the completion of an action. For example, a child's good working memory system would hold a mathematical problem, read by the teacher in the classroom, process the solution, and come up with the correct answer (mental action). In another example, somebody gives you a phone number that you have to

remember until you reach your calling device and dial that number. Psychologists devised numerous psychometric tests to assess working memory. "Digit Span" is a working memory subscale on Wechsler Adult Intelligence Scales-Fourth Edition (WAIS-IV; Wechsler 2008) and asks the examinee to repeat increasingly longer series of numerical digits, immediately after the psychologist reads these number sequences to them (e.g., 6-8-7-4-8-5-9). Naturally, the longer the number sequence is, the more intense the cognitive challenge for the examinee under evaluation. In an alternative and even harder part of the same subscale of WAIS-IV, the examinee has to repeat increasingly longer number digit sequences in a reverse order, immediately after they hear the number sequence. This version of the same subscale of WAIS-IV challenges the working memory system of the person even more, as the person here not only has to store temporarily the number sequence, but also manipulate mentally the information and repeat it in reverse order. Therefore, more cognitive reserves are needed for the completion of this task.

Working Memory Versus Short-Term Memory

Working memory is not synonymous to short-term memory, but a distinct cognitive system that could involve information, which could be verbal, visual, tactile, or from another modality or combination of modalities.

Short-and-long-term memories activate mostly the hippocampus, amygdala, and other subcortical areas, in an interplay, of course with, cortical areas, as well. Working memory mostly activates brain areas associated with executive functioning, such as the frontal lobe, particularly the prefrontal cortex, with an interplay of the parietal, visual, and temporal cortices, depending on the type of information being processed and the type of sensory modality. For example, verbal information in working memory will activate, among other areas, the prefrontal cortex, the left inferior parietal cortex, and temporal gyrus (Na et al. 2000; Eriksson et al. 2016).

Short-term memory is involved in the encoding, storing, and recalling information (in short term), with the possibility of moving information later into the long-term memory system (retaining information for the long-term). On the other hand, the working memory system's primary role is not to create short-or-long-term memories, but to store information for a short time period for the completion of a task or an action, as previously mentioned at the beginning of this entry.

Working Memory Is an Executive Functioning System

The working memory system is vital for our executive functioning, such as our everyday reasoning, planning, and decision-making. Therefore, in Baddeley and Hitch's "Working Memory Multi-component Model" (Baddeley 2003; Baddeley and Hitch 1974), a Central Executive Component helps us in attending to a task, while simultaneously suppressing irrelevant stimuli and coordinating and synchronizing subcomponents such as:

- (a) The Phonological Loop, which controls the store of verbal and spoken information, while preventing this information from decaying before being used. For example, remembering the food order of five customers for a few minutes, while repeating it in your head, until you finally enter it in the computer that communicates with the kitchen. The same phonological loop will be activated in the WAIS-IV subscale (Wechsler 2008) "Digit Span," which was described in the introduction.
- (b) The Visual Spatial Loop, which controls the store of Visual Spatial Information, in the same way as the Phonological Loop. For example, remembering how to get from point A to point B in a large complex building after you just looked at the map depiction of the building at the reception. Your working memory will keep that visual spatial information long enough for you to get to the room and floor that you need.

There are several neuropsychological psychometric measures that assess this by asking the examinee to look at pictures or maps for a few seconds before proceeding in using that information in problem solutions or manipulating mentally that visual spatial information.

- (c) The Episodic Buffer, which controls the temporary store of episodic information, which also interacts with the long-term memory storage and receives information from the other subcomponents and even creates a time sequence of the temporary stored events. Episodic information is the information that relates to our own personal experiences.

Limitations of the Working Memory System

The Working Memory System has capacity limitations (Cowan 2010). The demands of the task (e.g., how hard a mathematical problem is for the examinee), the length of the information (e.g., how many orders a waiter receives or how many numbers a phone number includes), how meaningful the information is for the individual (e.g., trying to temporarily store information for a math formula when you completely hate anything that has to do with math), and of course our individual differences (intellectual differences, emotional state of the person at the time, medication effects, and side effects, etc.) play an important role on how well the working memory system will function. Also, all these aforementioned variables play an important role on how successful the outcome of the working memory process will be (successful completion of the task). For example, how accurate you will be in remembering all 10 numbers in a number sequence you heard 5 min ago before you finally dial the number on your phone.

Working Memory Deficits

Individuals with impaired or deficient working memory systems could find it difficult to follow lengthy conversations, play chess or card games,

carry on with their trail of thoughts, finish a complex work action, follow multilegged directions, and even face difficulties in money exchanges that require temporary store of amounts or calculation of sale prices. Often, individuals with working memory deficit will complain also about reading and rereading the same text or page or are accused by others that they do not pay to conversations or directions intentionally. Some people could lose their jobs, bypassed in promotions, or not even be hired due to their poor working memory and inability to work on large projects. Children diagnosed with learning disorders and/or attention deficit hyperactivity disorder (ADHD) exhibit poor working memory. In fact scientists often state, and exhibit through their research studies, that ADHD is mainly a disorder of working memory (Sowerby et al. 2010).

Interventions

The interventions for working memory improvements are very similar (if not identical) to the interventions and ameliorating actions prescribed for individuals with ADHD. Offering information in smaller chunks, making sure that the individual processed the information by repeating the information that was just given to them, simplifying directions or information, using note-taking strategies in work or conversations, offering more time in reading material and tests that require working memory processing are just some examples. Medication used for ADHD and cognitive behavioral techniques could also help in severe cases of working memory deficits (Kobel et al. 2009).

Conclusion

Working memory is not another name for short-term memory. Working memory is a different system, which allows us to temporarily store information that we receive from different sensory modalities (from our visual, auditory, olfactory, and tactile senses) in order to cognitively manipulate that information and complete a task or an action. Our working memory has capacity

limitations and works concurrently with other cognitive systems (either in synchrony or in competition) to get us to the completion of the task or action. Many other variables, internal (such as our current emotional state or intelligence) and/or external (such as competing stimuli or environmental cues), could enhance the functioning of the working memory system or be detrimental to its functioning. Overall, working memory is an executive functioning system that we use every day and supports our actions and completing of tasks.

Working memory deficits could be the result of brain impairment, brain injury, medical treatment, mental disorder, and the combination of several causes. There are interventions and ameliorating actions offered in such instances.

Definition

Working women are those who seek paid employment, usually outside of the home.

Introduction

In the twenty-first century, an increasing number of women in industrialized countries are seeking full-time paid employment outside of the home (Galinsky et al. 2011). In the United States, men and women do not differ in their desire for higher-paying jobs. It is more and more common for women with children to seek out jobs with substantial responsibility. In the United States, this trend began during World War II out of necessity, as many men were involved in military service abroad and the country had an immediate need for manufactured goods and important services (Weatherford 2010). In the 1950s, 42% of women 18 years of age and older joined the workforce (Galinsky et al. 2011). By the latter twentieth century, the percentage had risen to 57% (Galinsky et al. 2011). Women's increasing presence in the workforce is related to changes in women's and men's roles in society as well as in the home. Nevertheless, many women handle the responsibilities of full-time, paid employment in addition to bearing and caring for children. In families in which both men and women work full time, women perform more of the childcare and housekeeping tasks than do men (United States 2015a). In the United States, the percentage of mothers who work outside of the home rose from 47.4% in 1975 to 70.3% in 2014 (United States 2015b).

Working Mothers

Women who have children and are employed outside of the home often find themselves struggling to manage the tasks of caring for children, managing the home, and navigating the demands of the workplace (Gersen and Jacobs 2001). Workplace stress has been found to have significant consequences for the health of mothers and their children. In a study from the 1980s, expecting mothers who felt that they had little or no control over increasing job demands in the workplace were at an increased risk of delivering preterm and having infants with lower birthweight (Homer et al. 1990). More recent researches on

the relationships between children's well-being and their mothers' work status have revealed evidence for both positive and negative relationships. In studies of children of single mothers, children of working mothers had higher achievement scores in school and had lower-level anxiety and depression than children of mothers who were not employed (Lucas-Thompson et al. 2010). In contrast, children of mothers who worked full time during the first year of age as compared to part time suffered more in terms of cognitive scoring and experienced more disruptive behavioral problems (Brooks-Gunn et al. 2010).

Mother's Work in Prehistory

The circumstances of working mothers in modern industrialized societies appear to be more demanding than those of mothers in prehistory. In prehistory, people lived in relatively small hunter-gatherer groups, in which men served as hunters and women participated not only in gathering but also in the invention and use of domestic tools, in food preservation, in the maintenance of home and family, in agriculture, as well as in childcare (Adovasio et al. 2007). The statuses women and men in hunter-gatherer groups have been described as comparable (Kelly 2013), unlike most modern societies in which men have higher status than women (Gersen 2009). The task of childcare was shared among all the women and men of the group (Sternglanz and Nash 2013). Changes in men's and women's gender roles toward that considered traditional in the United States and industrialized countries are likely to be related to the rise of agriculture after which men's work more often involved the physically demanding jobs related to farming and women's work more often involved activities related to food preparation, housekeeping, and caring for children (Alesina et al. 2013).

Conclusion

There is a significant trend of an increasing percentage of women working outside of the home.

Despite more women participating in the workforce, men's contribution of the work of the home (e.g., childcare and housekeeping) continues to be lower than women's. There is evidence of both positive and negative effects of mothers being employed outside of the home on children. When compared to the childrearing demands of mothers in prehistory in which multiple men and women from the group assisted with childcare, the circumstances of modern working mothers appear more demanding, as modern working mothers receive less support from fathers and other family members. There is a growing recognition that greater workplace flexibility is needed to support working families.

Definition

Interpersonal relationships that take place at work, with important implications for the individuals and organizations.

Introduction

Workplace relationships are unique interpersonal relationships with important implications for the individuals and organizations. Common relationships in organizational contexts include formal and informal mentoring relationships, leader-follower relationships, supervisor-subordinate relationships, and coworker relationships (Sias 2005).

Workplace relationships may function as decision-making, influence-sharing, and emotional support systems (Kram and Isabella 1985). Effective workplace relationships contribute to the overall well-being of both individuals and organizations by providing sources of social support and career development, increasing commitment, increasing morale, and reducing turnover (Kram and Isabella 1985). These relationships can also lead to aversive consequences. For example, close workplace relationships can provide organizations with some form of control over employees (Fine 1986) which may lead to unhealthy and dysfunctional work environments. Whether good or bad, the importance of workplace relationships is clear.

Workplace relationships share a great deal with the broader domain of interpersonal relationships. The evolutionary perspective focuses on the pressures that have shaped humans' approaches for relating with others. In fact, the human brain has evolved to the size and complexity it has in order to deal with our social networks (Dunbar 1998). The basic concept in workplace relationships is that certain patterns of behaviors (e.g., traits, strategies, preferences) have been selected from our ancestral past, influencing our cognitions and behaviors and leading to some degree of evolutionary success. The socioanalytic theory (Hogan and Blickle in press) provides a pertinent conceptual basis for understanding workplace

relationships assuming that the most important events in life occur during social interaction, and for adults, many of those interactions take place at work.

As it is known, people evolved as group-living animals, and every group has a status hierarchy and religion. Based on that, socioanalytic theory determines that social behavior rests on three powerful and probably unconscious motives: people need attention, acceptance, and approval (i.e., *get along*); people need status and power (i.e., *get ahead*); and people need structure and meaning (i.e., *finding a meaning*; Hogan and Blickle [in press](#)). In empirical research, these motives are captured mainly through personality traits and work values (Blickle et al. [2011](#)). They both are personal characteristics that explain individual differences in behavior at the workplace. Understanding the way each employee needs acceptance, power, and meaning and how successful they are at attaining these goals helps us understand the complexity of workplace relationships. For example, actors tend to need more social acceptance than hermits; politicians tend to need more status than social workers; and the religious orthodox tend to need more predictability and meaning than nonobservant (Hogan and Blickle [in press](#)).

Basic motives are therefore supposed to play a functional role in explaining a variety of work-related processes and outcomes, such as job satisfaction, motivation, commitment, and performance (e.g., Dose [1997](#)); absenteeism, risk behavior, trade union politics, and career development (Nicholson [2001](#)); and relationship development, workplace adjustment, and integrations (Teboul and Cole [2005](#)). Relationships in organizations result from automatic, yet measured assessments of non-zero-sum exchange and coordination opportunities with available others (Teboul and Cole [2005](#)). This perspective holds that much human inclination can be explained in terms of the adaptations that were functional in facilitating the survival and reproduction of our hominid ancestors. So, just like our ancestors, people with more social support, status, and control in their lives have a (work) survival advantage.

Conclusion

In closing, socioanalytic theory – which is grounded in an evolutionary perspective of human psychology – may serve as a vehicle for theoretical expansion and predictions about relationships in organizations, grounded in ultimate, rather than proximate, causation. Specifically, the social motives of getting along, getting ahead, and finding a meaning took hold because they helped early humans in hunter-gatherer bands resolve problems associated with resource scarcity and complex problem resolution (Teboul and Cole [2005](#)). Yet, these motivations are required in modern workplaces as well.

Definition

The question “Would you kill the fat man?” originates from the Trolley Problem – a thought experiment that explores morality. Specifically, the Trolley Problem creates morally complex scenarios that call for judgments as a means to explore the underlying rules that govern our moral instincts. David Edmonds wrote a book that explores this research called *Would You Kill the Fat Man?: The Trolley Problem and What Your Answer Tells Us About Right and Wrong* (Edmonds 2013).

Introduction

Imagine you are standing on the side of a railroad track. Up ahead you see five men bound to the

track with a train heading toward them. If you do nothing, the train will kill them. However, you can pull a lever which will cause the train to be redirected avoiding the five men. Unfortunately, on the redirected path, there is one man who is also tied to the track, and redirecting the train would kill him. What would you do? If your response is that you would pull the lever, then you are in agreement with four out of five of the responders to a BBC poll (Sokol 2006). The rationalization is a utilitarian argument: better one than five. Now imagine you are on a bridge, and beneath the bridge, there is a railroad track with five men tied to it. Rushing toward the five men is a train. If you do nothing, all five men will die, but standing beside you is a fat man. If you push him off the bridge, he will fall onto the railroad track in front of the train, and his body will be large enough to stop the oncoming train from reaching the five men. Better one than five? The same BBC poll now found three out of four responders reported that they would not push the fat man (Sokol 2006). What is the difference? Numerically, there is no difference. In both scenarios, one man is sacrificed to save five, and, when asked to explain why one scenario is morally permissible while the other is morally reprehensible, most responders could not give an explanation other than “it feels wrong” (Mikhail 2011).

The Trolley Problem

This philosophical puzzle, called the Trolley Problem, is one that has intrigued philosophers since the first version was proposed in 1967 by Philippa Foot in the Oxford Review (Foot 1967). “Would you Kill the Fat Man” by David Edmonds, a philosopher and researcher, explores the Trolley Problem and what this dilemma tells us about human nature and morality (Edmonds 2013; Edmonds et al. 2014). Edmonds begins by giving the reader a history of both the philosophers and the philosophical theories that have shaped the Trolley Problem debate. However, he goes beyond the philosophical explanations to include work from fields such as experimental psychology and neuroscience. By doing so,

Edmonds presents a book that is a roadmap to “trolleyology,” the field that has emerged from the Trolley Problem.

Philosophers, psychologists, and neuroscientists have all contributed to the field of trolleyology. However, the different disciplines have focused on answering different questions. Philosopher trolleyologists have focused on defining the morality in the Trolley Problem. Is it moral to pull the lever? Is it moral to kill the fat man? Psychologists are concerned with answering questions about the underlying factors influencing responses. Why do we respond in the manner that we do, and what can influence our responses? The distinction between the philosopher’s and the psychologist’s approach at answering the Trolley Problem is characterized by David Hume’s assertion that there is a fundamental difference between fact and value (i.e., what we should do and what we actually do; Hume 2012).

Even predating the presentation of the Trolley Problem, philosophers have proposed and discussed theories to explain seeming contradictions in morality that have since been applied to the Trolley Problem. Thomas Aquinas proposed the theory of the Doctrine of the Double Effect (DDE), which states that killing could be permissible if the purpose was self-preservation rather than the taking of another’s life. In the context of the trolley debate, the DDE has been cited as an explanation for why it is morally permissible to redirect the train. By redirecting the train, your intention is not to kill the one man. Rather, it is to save the five men. Ideally, that man would not be on the track, and, herein, the moral permissibility emerges because, while you can foresee it, the man’s death is not your intention. However, the DDE fails when applied to the Fat Man variation. In this scenario, while you may not wish the fat man to die, you are intending to use his body as means to stop the train. This action will result in his death (Edmonds et al. 2014). Judith Jarvis Thomson, who first proposed the Fat Man variation, attempted to solve this problem by arguing that there was a difference between diverting (e.g., pulling the lever) and creating (e.g., pushing the fat man) a threat, which is why the two dilemmas procure drastically different responses (Thomson

and Parent 1986). John Stuart Mill proposed the theory of two-tiered utilitarianism which states that there are rules that we must follow (e.g., do not kill). However, exceptions can be made to these rules if there are two or more in conflict with each other (e.g., do not kill versus saving five lives is better than saving one; Mill 2003). While these theories may explain some aspects of the instinctual morality behind the Trolley Problem, Edmonds introduces variations to the original scenario that brings into question whether any theory can singularly explain this philosophical puzzle.

Both psychologists’ and neuroscientists’ involvement in trolleyology has included empirical experiments into the philosophical debate and has introduced the possibility of an innate morality that influences our behaviors. When the Trolley Problem was posed to children under the age of five, they used intentionality to distinguish between acts that resulted in the same outcome (Mikhail 2011). Furthermore, the inclusion of intentionality shifted moral judgments. For example, the Trolley Problem was presented with the distinction that the person pulling the lever recognized the lone man tied to the track as someone they hated. This hatred caused them to want to kill that person independent of the desire to save more lives (Mikhail 2011). With this modification, the majority of responders found that it would be morally impermissible to pull the lever. Again, the utilitarian argument of saving five at the cost of one fails in this scenario. The addition of intentionality, even when all else is held constant, results in a shift in moral judgments. What is the underlying morality that is governing this switch in perceived morality?

Scientists, such as Jonathan Haidt and Joshua Greene, have proposed the possibility of a dual system where our behavior and our morality are influenced by both reason and emotion, wherein specific situations will cause the dual systems to be in direct conflict (Greene 2013; Haidt 2001). Neuroscience, specifically the use of brain imaging, has played a significant role in illuminating the distinctions between these two competing systems. Edmonds devotes a significant portion of the book to discussing the work of Joshua Greene,

who was the first to use a neuroscientific perspective to answer trolley-related questions. Greene proposed that brain imaging could enable the visualization of the competing dual system of reason and emotion (Greene 2013). The ventromedial prefrontal cortex (VMPFC) is the part of the brain responsible for the emotional response, whereas the dorsolateral prefrontal cortex (DLPFC) is responsible for cognitive control (i.e., reason). When presented with the Fat Man variation, participants had increased activation in the VMPFC. Contrarily, when presented with the option of pulling the lever, participants showed increased activation in the DLPFC. Additionally, when the Trolley Problem was presented to individuals who had damage to their VMPFC, resulting in a stunted emotional response, they were more likely to believe that it was morally permissible to push the fat man (Greene 2013).

Joshua Greene likens the dual systems to a camera with both manual and automatic settings where emotional responses are the automatic setting and the planned reasoned responses are the manual setting (Greene 2013). Switching to the manual mode requires time and effort, which explains why the longer a person was given to think about the Trolley Problem, the more likely they were to decide that it was morally acceptable to save the larger number of people even at the expense of the one (Suter and Hertwig 2011). Cognitive load also impacts decision making where, if the participants were completing another task when they were presented with the Trolley Problem, they were more likely to give an emotional response (Suter and Hertwig 2011).

Greene has proposed a theory for the underlying factors driving our response to the Trolley Problem, which is an amalgamation of the theories proposed by philosophers and the findings from the experiments conducted by scientists. Greene proposes that the response to pushing the fat man originates from (1) the up-close-and-personal effect and (2) our aversion to intentional harm. The up-close-and-personal effect comes into play due to the physical act of pushing someone, whereby it is a personal interaction that results in an increased emotional response (i.e., activation in the VMPFC). You would be using a

part of your body to kill another person. Comparatively, using a lever to kill someone is an impersonal interaction. The aversion to intentional harms fits well with the DDE where the same outcome can produce different moral judgments based on intentionality. Overall, Greene believes that, when only one of those factors is present, reason or the DLPFC is in the “driver’s seat” and guides our moral response. However, when both of these factors are present in a situation, the result is a strong emotional reaction. The VMPFC is activated, and there is a strong aversion to pushing the fat man (Greene 2013).

While the brain mechanisms underlying the moral response to the Trolley Problem may be a proximate explanation, the question still remains as to the ultimate reason for these processes. Edmonds (2013) discusses potential evolutionary explanations for our moral responses. First, there is the possibility that we have a stronger emotional response to threats that were present in our evolutionary environment. This could further explain the disparity of responses between pushing the fat man and pulling a lever. The threat of pushing or being pushed was present in our evolutionary history, and, therefore, there may have been stronger selection pressures to develop an aversion to it in comparison with pulling a lever. Furthermore, we have evolved heuristics for behavior in order to better respond to threats in our environment. Although these heuristics evolved in order to better avoid threats to our survival, they may not always serve us well in our modern world. This is particularly true when heuristics are in opposition to each other. In the Trolley Problem, the heuristics of “do not kill” and “save lives” are in direct opposition with each other, and our heuristics have not evolved sufficiently to deal with this conflict (Edmonds, 2013; Edmonds et al. 2014).

Since 1967, trolleyology has expanded to include variations on the original scenario and various competing theoretical explanations for the underlying morality. However, there are critiques of trolleyology specifically concerning its generalizability. Those in the field of trolleyology appraise the Trolley Problem as a way to investigate our innate morality. However, many question whether the Trolley Problem contains any real-

world application, given that real-life occurrences do not follow the limitations that are placed in the trolley scenarios. For example, if you were to actually be in the scenario depicted in the Trolley Problem, you would have more than two possible outcomes. Perhaps, the train would be able to stop before reaching the five men, or perhaps there is enough time for you to untie the men before the train reaches them. In the fat man scenario, there are more problems, such as the possibility that the fat man would fight back (resulting in you not being able to throw him off the bridge), or perhaps if you did throw him, he would not land in the correct spot. Even if he did land correctly on the railroad, there is the possibility that his body would not stop the train. Even if all went well and the fat man did stop the train, there would be legal repercussions for you, the pusher. All of these factors are argued to detract from the real-world application and, therefore, the utility of trolleyology. Edmonds, however, argues that what trolleyology does is separate the white noise and allows for the examination of our innate morality (Edmonds 2013; Edmonds et al. 2014). Without all these extraneous factors, what do our moral instincts tell us to do?

Conclusion

Although the Trolley Problem and its underlying explanation is still an ongoing debate, David Edmonds' *Would You Kill the Fat Man* presents a comprehensive guide to the history, theoretical explanations, and contributors to trolleyology.

Yanomamö. Well known for their highly aggressive warriors and conflict over women, the Yanomamö provide insight into how tribal men may have used positions of status to acquire more mating opportunities. Most notably studied by anthropologist Napoleon Chagnon (2013), the Yanomamö were documented in his fieldwork to exist in a nearly constant state of warfare. Chagnon studied the Yanomamö over the course of approximately 25 trips to the region, spanning 35 years. In that time, Chagnon provided extensive documentation of their social structure and the influence that leadership and high status positions have on mating success within their polygynous society.

Synonyms

[Yanomami](#)

Definition

Tribal people located in South America known for their aggressive lifestyle and chronic warfare between villages.

Introduction

Along the borders of Venezuela and Brazil resides an Indigenous group of people called the

Social Structure and Sexual Access

Overall, the Yanomamö are composed of approximately 25,000 people that make up roughly 250 tribes. Each tribe varies in the number of individuals it encompasses, yet has a standard social hierarchy that defines the norms for appropriate behaviors among members. The greatest division in the hierarchy is the large inequality between the sexes. Women and girls represent the lesser of the sexes and are given very little social power. In contrast, males are positioned toward the top of the social hierarchy and are treated with great respect.

While observing the Yanomamö, Chagnon (1992) reported a state of chronic warfare that

exists between the various tribal villages. Chagnon (1988) has suggested that the chronic warfare is the result of males seeking female mating opportunities. The Yanomamo display a polygynous mating system, and as a result, females are highly sought after. This competition for mates is argued to have contributed to the high rates of warfare between tribes. Indeed, tribal warfare provides men the opportunity to compete for direct access to mating opportunities, as well as resources and status that indirectly attract women.

Although Yanomamö women are restricted in their social mobility, the men have many opportunities for upward mobility. In particular, two prominent positions within the Yanomamö society are Unokai and headmen. Each are high status positions that entitle men to greater mating opportunities. Headmen are present within each village and serve as a primary political leader. This specific position is obtained based on familial ties, such that the male who has the most kin within their patrilineage is granted the position of headman. This title presents responsibility and reward. The headman in each tribal village must make major decisions and coordinate its members. Ultimately, the headman is responsible for overseeing the village. Chagnon documented a range of leadership styles of Headmen, from relatively calm to tyrannical (Chagnon 2013). The Unokai are warriors who have killed another person or were responsible for the death of another during war. The aggressive acts of the Unokai provide protection to their village, as it deters other villages from attacking them and are therefore awarded higher status among the group.

The high degree of responsibility and risk accepted by Headmen and Unokai does not go unrewarded. Indeed, Chagnon reported that Headmen and Unokai have more wives relative to other male members of the tribe. This is predominantly achieved via arranged marriages in which a father or close male kin negotiates payment for marriage. High status men have greater access to resources to offer as payments and therefore enjoy greater mating access as well as

higher quality mates. Chagnon (2013) provided an example where a headman had as many as 11 wives. Furthermore, Unokai on average have more extramarital affairs, wives, and children (Chagnon 1988) than lower-status members of the group.

Conclusions

The Yanomamo provide a key illustration of the association between status, warfare, and sexual access. The Yanomamo, as described by Napoleon Chagnon, exist in a constant state of warfare. That warfare serves, at least in part, the function of increasing access to mating opportunities. Moreover, men who are the most successful warriors and/or who have high social status within the group are granted greater sexual access to mating opportunities.

Yo-Heave-Ho Theory

- [Yo-he-ho](#)

Yo-he-ho

Demetra Themistocleous and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Origin of language; Social interaction source; Yo-Heave-Ho theory

Definition

The growls and moans humans used for coordinating their bodily activities when they performed teamwork are the origin of language, as per the belief of the early *Yo-he-ho* theory of language.

Introduction

Verbal communication commenced as growls, moans, and rhythmic chants which occur from the overwrought efforts of ancient menfolk to move a boulder or heave a rock, as it is suggested by the *Yo-he-ho theory* (Mandavilli 2016). Every time these people were working hard to move something heavy, they produced a sound which slowly developed into words such as *heave* and *lift*. Therefore, if they didn't want to memorize their favorite growl sound and use it over and over again, this sound would seem to be random. However, these growls would not be accounted as words in a lingual meaning since they would seem unlikely to fall into consonant-vowel patterns (Rice 1976).

The *Yo-he-ho theory* does, however, have a benefit since it is responsible for the inducement, the cause, and the aim of the language. It describes language as emerging from a need to communicate and for making the engagement among men possible in organized activity, rather than seeing language resulting from a cave dweller imitating

an animal's howl to assist him while he was away for his dinner (Barber 1965). The *Yo-he-ho* theory can be found in the literature as *Yo-heave-ho theory* and *Social interaction source*; all of them proposed that the origin of speech begun as growls and moans (Mandavilli 2016).

Notwithstanding the above, evolution plays an important role since it claims that human society developed gradually because men began thinking of new things to do and began doing them collectively. What makes this theory interesting, however, is the query of what motivates the speechless cavemen move a boulder in the first place since language emerged from the growls and moans of their teamwork. Unfortunately, the origin of grammatical structure is not explained or how a social system got started void of language (Rice 1976).

Conclusion

The notion that the growls and moans humans used for coordinating their bodily activities when they worked collectively initiated the speech, as reflected by the *Yo-he-ho* theory. The growl and moans made by humans while doing hard physical work resulted in providing a language. The limitation of this theory is that the origin of the vocables is not explained, and therefore it is not accountable for the words of the various languages worldwide. The idea of this theory is unrealistic since a small percentage of words can be ascribable to such sources.

[Low-status males](#)

Definition

Some theorists have contended that suicide terrorists are low-status males who are younger in age and have poor mating prospects.

Introduction

The data indicate that suicide attackers tend to be young males in their early twenties. Statistics on Middle Eastern suicide terrorists reveal that the mean age of attackers is 21 with an age range of 12–64 (Benmelech et al. 2012).

Theoretical Considerations

Kanazawa (2007) and Thayer and Hudson (2010) argued that the condoning of polygyny in the Middle East places pressure on young males who lack social status and capital relative to older males to enact violent means to obtain mates via sexual access manipulations (Kanazawa 2007). Though competition among males increases risk-taking behavior, Kanazawa's hypothesis is theoretically untenable and is not supported empirically. Lawson et al. (2008) countered that in contexts where older males monopolize females such as

gerontocratic societies males should spend their younger years acquiring resources and status in order to successfully obtain mates later in life. Moreover, the percent of ever married men in Muslim and non-Muslim nations are comparable (Lawson et al. 2008).

There are several alternative evolutionary explanations for the young age of male suicide attackers with varying degrees of support. While the polygyny component of Kanazawa's hypothesis is unsubstantiated, sexual access manipulation might play a role in an individual male's motivation to commit a suicide attack (see ► [Sexual Access Manipulation](#)). The promise of 72 virgins in the afterlife as a reward for martyrdom, though not a universal Islamic doctrine, is perpetuated by some Islamic terror organizations. And, according to Hafez (2006), belief in the attainment of rewards in the afterlife is amongst the top three motivations for suicide attack among Palestinian combatants. Sexual access manipulation might also operate through the veneration of suicide terrorists as martyrs by local communities as male reproductive success is positively correlated with social status (Smith 2004). However, there is at present no evidence that male suicide terrorists have lower status compared to other males in their society as measured by income and education (Atran 2003).

Another evolutionary theory of suicide terrorism proposes that terrorist organizations manipulate followers into embarking on suicide missions in part by manipulating evolved kinship psychology (see ► [Kinship Psychology Manipulations](#)). This functions via the deceptive activation of kinship recognition. Kin altruism is based on Hamilton's rule ($rb > c$) where r is the degree of genetic relatedness, b is the reproductive benefits to related kin, and c is the cost to the agent (Hamilton 1963). Therefore, an organism should act altruistically if the reproductive benefits to its kin outweigh the costs of the act to the organism, thus increasing the organism's inclusive fitness. Kin selection demonstrates how traits that harm individual organisms can be maintained by natural selection (Liddle et al. 2011). Hypothesized cues of genetic kinship among humans as listed in Qirko (2004, 2009) include physical proximity

during development. Qirko (2009) predicted that terror organization that recruit individuals for suicide missions would, among other things, tend to seek out individuals who are younger in age. Terror organizations often recruit suicide attackers before they reach their twenties; recruits are separated from their genetic kin and trained in isolation from their natal families and communities (Qirko 2004, 2009).

Conclusion

There are several evolutionary theories that seek to account for the young age of male suicide attackers. Young males do not appear to be excluded from the mating market as some have suggested. More research is necessary to understand the association of young males with suicide attack from an evolutionary perspective.

Definition

A range of physical cues (e.g., waist-to-hip ratio) convey important information about the age of a potential mate and their ability to reproduce.

Introduction

The selection of a high quality mate is of fundamental importance. In particular, the identification of healthy, sexually mature, fertile individuals enhances reproductive success. Hence, a range of physical cues advertise these qualities. The current entry highlights the manner in which a range of physical features (i.e., waist-to-hip ratio, fluctuating asymmetry, and voice) signal youth and fertility. Previous research indicates that cues (and the attractiveness of these cues) are often related. For example, those with attractive faces tend to have attractive bodies (Thornhill and Grammer 1999), odor (Rikowski and Grammer 1999), and voices (Collins and Missing 2003). This may reflect the influence of the same underlying mechanism, for example, the sex hormones which shape male and female voices at puberty also influence the development of other secondary sexual characteristics.

Correlations between attractiveness ratings based on different cues are however often low, and the extent to which these cues signal the same aspect of mate quality is debated. According to the multiple message hypothesis, different cues signal different aspects of mate quality (e.g., current reproductive state and immunocompetence) and information provided by these various cues lead to an assessment of overall mate quality. It is argued that raters may emphasize different cues when prioritizing particular elements of mate quality (e.g., fertility) or when focused on different relationship types (e.g., short-term sexual relationships). In contrast, the redundant signal hypothesis (or back up signal hypothesis) proposes that each cue conveys similar information, which lowers the likelihood of inaccurate judgments and the selection of a poor quality mate. Specific cues may be favored in particular contexts such as when observing potential partners

from a distance or when visual information is not available.

It should also be noted that a selection of cues are presented only and others such as complexion and teeth (Hendrie and Brewer 2012) also convey important information relating to youth and fertility. Furthermore, research investigating this subject has predominantly focused on ratings of static images. Body movements such as dance have an important role in human courtship, and may also convey important information. For example, dance may reveal a range of important physical qualities including coordination, muscle strength, and flexibility. Indeed perceived dancing ability is related to physical condition (Hugill et al. 2009), and women's dance and gait are rated as more attractive when performed during the high fertile phase of the menstrual cycle (Fink et al. 2012). Future research should further consider the importance of movement in the advertisement of youth and fertility.

Waist-to-Hip Ratio

Prior to puberty, girls and boys display a similar waist-to-hip ratio. At puberty, estrogen stimulates the accumulation of fat in the gluteofemoral region (buttocks and thighs) and inhibits accumulation in the abdominal region, while testosterone exerts the opposite effect. Hence, for healthy Caucasian men and (premenopausal) women, waist-to-hip ratios range from 0.85 to 0.95 and 0.67 to 0.80, respectively (Marti et al. 1991). For women, waist-to-hip ratio rises after childbirth and menopause. Therefore, waist-to-hip ratio provides a reliable indication of female age and reproductive status (see Singh 2002 for a review). In addition to age and reproductive status, waist-to-hip ratio may signal other aspects of health condition. For example, waist-to-hip ratio is associated with susceptibility to breast cancer, cardiovascular disease, diabetes, and ovarian cancer (e.g., Connolly et al. 2002). With regards to reproductive health, waist-to-hip ratio is associated with regularity of ovulatory cycles, likelihood of conception, and offspring quality (e.g., Zaadstra et al. 1993).

Previous research demonstrates that women with low waist-to-hip ratios (i.e., those with a ratio of 0.70) are identified as more attractive, healthy, and desirable as relationship partners than those with high waist-to-hip ratios (Singh 1993). Indeed, optimal waist-to-hip ratios also activate the neural reward centers in men (Platek and Singh 2010). Research demonstrating the impact of waist-to-hip ratio on perceived attractiveness has employed a range of methodological techniques. These include documenting waist-to-hip ratio measurements of beauty pageant contestants or *Playboy* playmates, and presentation of line drawing stimuli, computer manipulated photographs, and photographs of those engaging in surgical procedures. Women with a low waist-to-hip ratio are regarded as attractive in a range of cultures including Cameroon, Indonesia, Samoa, and New Zealand (Singh et al. 2010). However, Marlowe and Wetsman (2001) demonstrate that men in hunter-gatherer (Hadza) societies rate women with high waist-to-hip ratios as more attractive, healthy, and desirable as a wife, illustrating the importance of environmental condition and context.

Indeed, it has been argued that body weight and body mass index have a greater impact on female attractiveness than waist-to-hip ratio and that the increased attractiveness of those with low waist-to-hip ratio reflects the relationship between attractiveness and body weight (e.g., Tovee and Cornelissen 1999). However, research utilizing photographs of those undertaking micrograft surgery which lowers waist-to-hip ratio while maintaining body mass index demonstrates that low waist-to-hip ratio influences attractiveness (Singh et al. 2010). Furthermore, waist-to-hip ratio and body mass index may each influence perceived attractiveness. For example, whereas body weight indicates physical health and the resources available to support pregnancy and lactation, waist-to-hip ratio signals youth and fertility. Hence, Singh (1993) states “Neither body weight nor WHR alone is associated with female attractiveness. Highly attractive women must have a low WHR; yet deviation from normal body weight, either lower or higher, reduces attractiveness and perceived healthiness” (p. 303).

Fluctuating Asymmetry

Though some physical features (such as waist-to-hip ratio) are restricted to the face or body only, others influence both facial and bodily attractiveness. One such cue, fluctuating asymmetry, refers to the deviation from perfect symmetry in bilateral physical traits for which differences between left and right sides are on average zero. It is an important index of genetic and phenotypic fitness and reflects the ability of an individual to cope with environmental stressors during development. Factors increasing fluctuating asymmetry include exposure to environmental pollutants, extreme temperatures, and parasites during development. Low fluctuating asymmetry is therefore a nonfalsifiable signal of immunocompetence and developmental stability. Previous research has consistently identified a relationship between fluctuating asymmetry and both facial and bodily attractiveness.

Important relationships occur between fluctuating asymmetry and a range of life history outcomes suggesting that it conveys important information about the quality of potential mates which impacts on subsequent reproductive success. For example, Moller et al. (1995) report that breast fluctuating asymmetry is higher in nulliparous women than those with at least one child, and breast fluctuating asymmetry is a reliable predictor of (age independent) fecundity. Similarly, Waynforth (1998) reports that in men, low fluctuating asymmetry is associated with low morbidity, greater number of offspring, lower age at first reproduction, and greater number of lifetime sex partners.

Voice

Adult voice pitch is sexually dimorphic with male fundamental frequency significantly lower than female frequency. These differences reflect vocal fold enlargement and vocal tract lengthening during puberty and are shaped by sex hormones at puberty. Specifically, estrogen and progesterone influence the development of the female voice, while testosterone influences the male voice (Abitbol et al. 1999). Previous research has established that men and women prefer

relationship partners with higher and lower pitched voices, respectively. These preferences have been observed when using both natural and experimentally manipulated stimuli and in both Western industrialized and hunter-gatherer populations (e.g., Apicella and Feinberg 2009). There may however be an “accepted range” of voice pitch. Borkowska and Pawlowski (2011) report that higher pitched female voices are rated as more attractive up to an optimal pitch, with the highest pitched voices rated as less attractive. This may reflect the perception that these voices are “babyish” and associations with sexual immaturity.

Women adopt a higher pitched voice when communicating with attractive men (Fraccaro et al. 2011). While this change in voice pitch may signal sexual interest, research suggests that deliberately lowering male voice pitch or raising female voice pitch does not necessarily increase vocal attractiveness. Men raising voice pitch and women lowering voice pitch are however rated as less attractive (Fraccaro et al. 2013). Voices appear to convey important information about the speaker and those exposed to voice samples and photographs are able to estimate a range of physical characteristics such as age and height to a similar degree of accuracy (Krauss et al. 2002). Age appears to be an important element of the vocal cue. Men with low voices are perceived to be older (Feinberg et al. 2005), and the voices of women at peak reproductive age (19–30 years) are rated as more attractive than those aged 11–15 years or 50–65 years (Roder et al. 2013).

Female voice variation occurs during menstruation, pregnancy, and menopause (Caruso et al. 2000); therefore, voices also convey important fertility oriented information. In particular, female voices display a higher pitch during the fertile phase of the menstrual cycle (Bryant and Haselton 2009). Furthermore, the voices of naturally cycling women are most attractive and produce the greater physiological response in raters during the high fertility phase of the menstrual cycle (Shoup-Knox and Pipitone 2015). Similar differences do not occur in women using hormonal contraception. Voice pitch is also related to important reproductive outcomes. Men with lower pitched voices and women with higher pitched

voices report greater reproductive success (Apicella et al. 2007; Atkinson et al. 2012).

Conclusion

The selection of a sexually mature, healthy, fertile mate increases reproductive success and a range of physical cues convey this information. Previous research has identified the manner in which specific traits are associated with physical quality (e.g., age and likelihood of conception) and the extent to which these influence mate preferences. Additional research is required to understand the relative importance placed on each cue and the extent to which factors such as context and movement influence the salience of each trait.
